A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH.

THURSDAY, NOVEMBER 3, 1887.

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION.

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873–76 *under the Command of Capt. G. S. Nares, R.N., F.R.S., and of the late Capt. F. T. Thomson, R.N.* Prepared under the Superintendence of the late Sir C. Wyville Thomson, Kt., F.R.S., &c., and now of John Murray, one of the Naturalists of the Expedition. Zoology—Vols. XX. and XXI. (Published by Order of Her Majesty's Government, 1887.)

THE twentieth volume of the "Zoological Reports of the Voyage of H.M.S. *Challenger*" contains three memoirs, of which the first is "On the Monaxonida," by Stuart O. Ridley, M.A., and Arthur Dendy, B.Sc. The collection of this group of the Sponges was, in the first instance, intrusted to Mr. Ridley, who, to hasten the completion of the work, was afterwards joined by Mr. Dendy.

When about ten years ago Prof. Zittel gave the name Monactinellidæ to an order of Sponges, the position of this group became for the first time clearly defined. Prof. Sollas, some five years later, pointed out that Zittel's name implied a wrong idea, for that the characteristic spicules of the group were just as often "diactinal" as "monactinal," and suggested that, as both these forms were, however, "monaxonid,"—that is, having only one axis, which, in the case of the diactinal forms, passed through both the rays—the group should be called Monaxonidæ. As this group represents a division higher than that of a family, for which the termination "idæ" stands, all subsequent writers have adopted the name "Monaxonida." This group Sollas now regards as a tribe of the sub-class Demospongiæ, but the authors of this Report consider it with Zittel as one of the orders of the class.

The classifications of Gray, Bowerbank, Schmidt, or Carter, have now little but historic interest, while as for the more recent writers it would even seem as if each new series of novelties described necessitated a fresh shuffling of the orders, sub-orders, and families.

In the chapter on the anatomy and histology of the group the subject of the spicules is fully treated. It appears to us that no apology was needed for passing over the writings of Bowerbank on these forms; and when the authors too modestly refer us for further details as to the nature, &c., of siliceous spicules to, among other volumes, those of this author, we prefer, without meaning the slightest reflection on his great labours, to turn instead to the pages of the present Report.

The very difficult subject of a nomenclature for the spicules is treated at some length. Those of this order are divided into the two classes of "mega-" and "micro-" "sclera." In each of these there is a very numerous series of forms, all of which get separate names, founded on some prominent distinguishing character of the spicule. Let us hope that the majority of these names may find acceptance with writers on this group of Sponges, so that one difficulty in its study may be removed.

Passing over the descriptions of the spongin, the arrangement of the skeleton, and those of the ectosome and choanosome, we must briefly notice a very remarkable structure, which would appear to be quite unique, and which is found in a Sponge (*Cladorhiza tridentata*, sp. n.) from a depth of 1600 fathoms. The little Sponge in which this occurs is in shape somewhat like a miniature watch-stand. Embedded in the soft tissues, all around the upper margin of the concavity, a large number of small yellow globular bodies are found. Each globular body consists of a central, more deeply staining and granular portion, surrounded by and embedded in a matrix of faintly staining, perfectly hyaline ground substance. The granular appearance of the central mass is owing to very numerous embedded cells; these are irregular in shape and nucleated. Other peculiar cup-shaped bodies occur towards the periphery of the Sponge, embedded in the matrix. The authors think it probable that the cup-shaped bodies are aggregations of glandular cells similar to those met with in the ectosome of some other Sponges, and hint that the whole structure may be phosphorescent, and serve to attract minute organisms upon which the Sponge feeds. In regard to the canal-

system the authors' general conclusions are quite in accord with those of Vosmaer and Polejaeff. In the classification adopted the order is divided into two sub-orders, Halichondrina and Clavulina. The first of these is divided into four families: I. Homorrhaphidæ, II. Heterorrhaphidæ, III. Desmacidonidæ, and IV. Axinellidæ; the second into I. Suberitidæ, and II. Spirastrellidæ.

Over 200 species or well-marked varieties are described from the *Challenger's* dredgings, but all the new species were first diagnosed in the *Annals and Magazine of Natural History* during the course of last year (1886).

In reference to the geographical distribution, the authors remark that one cannot fail to notice the small number of stations at which these Sponges were found. Out of a total of 277 distinct stations, only 50 are represented as stations for these Monaxonids, and these are supplemented by 20 localities to which no station-number is attached; and these latter were not, it is to be assumed, deep-sea stations. We cannot agree with the suggestion that these forms were overlooked amongst the "rubbish" in sorting out the contents of the trawls and dredges; or with the idea that owing to their fragility they may have been destroyed. Doubtless the true explanation is that "the Monaxonida are not, on the whole, a predominant group in deep water."

While not a predominant group in deep water, still no less than 24 species were found at depths between 1000 and 2000 fathoms, while 46 occurred between depths of 200–1000 fathoms, and 140 species, or exactly double the previous number, were found at depths of from 0–200 fathoms.

The scarcity of Monaxonid Sponges at very great depths is somewhat compensated for by the unusual interest attaching to the species which do occur. Among other facts we find that, while the shallow-water forms are characteristically more or less shapeless in their external form or at the very most digitate or ramose, those from below the 1000-fathom depth have almost without exception beautifully symmetrical and definite shapes.

One of the most beautiful and extraordinary of the species described and figured is *Esperiopsis challengeri*, Ridley: it was taken in some quantity off the east of Celebes Island from a depth of 825 fathoms. From a slightly expanded attached base a slightly curved stem arises, which is composed of densely packed and firmly united stylote spicules: this stem is compressed laterally; numerous short simple branches arise from the concave edge at gradually increasing intervals, the longest of the internodes being at the top; the main stem and each of these branches terminate in fleshy sponge lamellæ, of which there may be six or seven in an apparently full-grown specimen. Each lamella presents the form of a deeply concave, transversely elongated cup: the oscula are confined to the convex surfaces of the lamellæ; the pores are found on the concave surfaces. This species is figured on Plate XVIII. Fifty-one plates accompany this Report.

The second Report in this volume is a supplement to Dr. L. von Graff's Report on the Myzostomida. It includes the description of seven new forms besides fourteen previously described species, all received from Dr. P. Herbert Carpenter; these were found by him while investigating the *Challenger* Crinoids. The author refers to the so-called cysts of *Antedon rosacea*, but declares that in no one case did he find therein any trace of a Myzostoma or any other encysted organism. On the contrary, both in the various pinnule deformities and in the arm swellings, he found a roundish brown foreign body, which was apparently the cause of the deformity. As to the nature or origin of this body nothing has been determined. Three plates of the new species and one of the cysts of *Antedon rosacea* accompany this Report.

The third Report is on *Cephalodiscus dodecalophus*, McInt., by Prof. W. C. McIntosh. This very remarkable new type of Polyzoon was dredged in the Strait of Magellan, and was, when first found, placed among the Compound Ascidians. The late Mr. Busk, Prof. Allman, and Prof. McIntosh, referred it to the Polyzoa. At first sight the flexible cœnœcium might easily be taken for a sea-weed, but it would seem to spread over the surface of the ground and not to grow erect. Of the numerous branches many anastomose; the general surface is spiny or fimbriated; the interior of the stem and branches contains an irregular series of wide canals. The Polypides are described as being perfectly free and at liberty to wander anywhere along the chambers, or even externally through the apertures. Each adult Polypide measures, from the extremity of the cephalic plumes to the tips of the pedicel, about 2 millimetres. Large buds in various stages of development arise from the Polypides. The twelve branchial plumes are very conspicuous. The author thinks that Cephalodiscus approaches Rhabdopleura. In an important appendix, by Mr. Sidney F. Harmer, the affinities of this form to Balanoglossus are ably pointed out, and he thinks that this genus (and perhaps Rhabdopleura also), must be removed from the Polyzoa and placed in Bateson's group of the Hemichordata. Seven plates and numerous woodcuts illustrate this Report.

Volume XXI. contains but one Report, that on the Hexactinellida, by Prof. F. E. Schulze, of the University of Berlin. This volume is issued in two parts, the first that of the text, comprising over 500 pages, and the second consisting of an atlas of 104 plates.

This is one of the most important of the fifty-three Reports hitherto published. This group of Sponges early attracted the special attention of the late Sir Wyville Thomson; and it was his intention to describe the Hexactinellids of the *Challenger* Expedition, but the work had scarcely been seriously commenced at the time of his death. It was fortunate that the services of Prof. Schulze were secured for the writing of this monograph, which is a most acceptable and welcome addition to our literature of this group.

In this Report, besides the collection made by the *Challenger*, the results of the previous cruises of the *Lightning*, *Porcupine*, *Knight Errant*, and *Triton* are also detailed, and the material has been further increased by a collection made at Japan by Dr. Döderlein.

The Hexactinellids are those forms of the Sponges in which the siliceous spicules belong to the triaxial type. Omitting the eighteenth century reference to a Sponge belonging to the genus Dactylocalyx, Dr. Gray was the first in the present century to describe some peculiar "glass rope-like" structures in the British Museum under the name of Hyalonema; though without recognizing until long afterwards their real affinities. This was in

1832, and in the following year Quoy and Gaimard figured and described their *Alcyonellum speciosum*. During the next twenty years only five more species were added to the list, the beautiful *Euplectella aspergillum*, Owen, being the most remarkable of these. The last twenty-five years have, however, witnessed an ever-advancing progress in our knowledge of these Sponges, thanks to the labours of Gray, Bowerbank, Wyville Thomson, Schmidt, Kent, Carter, Marshall, Sollas, and, above all, of Zittel, which labours have now culminated in the present Report.

It is scarcely to be wondered at that the beautiful glassy frame-work and the charmingly diversified spicules which form their "skeletons" have always attracted attention to these Sponges—an attraction that will be greatly intensified by the publication of this volume.

The Report opens with a general historical introduction, and then passes on to details of the forms and structures to be met with in the group: herein we find the nomenclature adopted for the spicules. This is followed by the description of the genera and species. It is pleasant to find in the synonymy and specific details that great pains have been taken to mention the work of all previous labourers in the field, and the author shows a due and kindly appreciation of what has been done by those who often had but little light to guide them on their way.

It is not easy to give any analysis of so elaborate a memoir, in which twenty new genera and sixty-five new species are described; while with scarcely an exception the numerous species already described are not only alluded to, but many fresh details are given about them. When it is recollected that but fourteen years ago only thirty species of this group of Sponges were known, the progress of our knowledge of them, it will be recognized, has been great.

These Sponges seem to be widely distributed in all the oceans; the largest number of forms—fifty-seven—being found in the Pacific Ocean; next comes the Atlantic Ocean, in which twenty-four species were found; while only sixteen were found in the South Indian Ocean; but it must not be forgotten that the South Indian Ocean has been very slightly investigated.

As to the bathymetrical distribution of the Hexactinellida, they would appear to be met with in depths of between 95 and 3000 fathoms, being more numerous between the depths of 100 and 900 fathoms, decreasing somewhat between those of 900 and 2500 fathoms, and again markedly diminishing between the depths of 2500 and 3000 fathoms, while below this depth no Hexactinellida Sponges have been found. Euplectellids seem to have a wide range, being met with at the moderate depth of 95 fathoms, and then being pretty evenly distributed down to a depth of 2750 fathoms. The four species of the new genus Holascus frequent great depths, varying from 1375 to 2650 fathoms. The maximum depth as yet known for any of these Sponges is that of 2900 fathoms, at which depth *Bathydorus fimbriatus* was found in the middle of the North Pacific Ocean.

It would be obviously impossible to give even a brief summary of the very remarkable new forms described in this splendid memoir of Prof. Schulze, and it is difficult to convey a correct notion of the beauty of the illustrations forming the large atlas of plates which accompanies the text. The diagnoses of the genera and the descriptions of the species are what one would expect from the well-known skill of the author.

We do not altogether agree with him when he writes that, "after a detailed investigation of a group of animals, it is incumbent on every naturalist who accepts the evolution theory to attempt the appreciation of his results in their relation to the phylogeny of the group." Looking at his array of facts, is it not possible for the thoughtful worker to bear in mind the incompleteness of the phylogenic record, and reverently to wait for more light? There may be nothing to object to in the stately genealogical tree of the Hexactinellida represented on p. 495, but is it not built up on but an incomplete and scanty framework?

One departure in this Report from the ordinary custom in the description of species we notice with regret—viz. that there is no synonymic list affixed to the species, neither are we referred, in connection with each form, to the place or places where it has been previously described. It seems scarcely necessary to point out the inconveniences attending such a style, or the great uncertainty it may on occasions give rise to. The volume opens at the description of *Rosella antarctica*, Carter. To find where it was first described by Mr. Carter we are obliged to refer to the synonymy affixed to the diagnosis of the genus; but here we get no certain information as to how many of the quotations given refer to this species; and this is of course much more confusing when we come to investigate a genus abounding with species, like, for example, Hyalonema. Indeed, by this method an author is very apt to overlook the fact that several writers may refer to the same species under quite different names, and a curious case of this nature, we suspect, occurs under Hyalonema. Dr. Gray, wrongly trusting to a Museum label, replaced the name *Hyalonema sieboldii*, which he had given to the first known species of this genus in 1835, by that of *H. mirabile*, under the impression that he had so named it in the "Synopsis of the Contents of the British Museum," 1832 (misprinted 1830), the year he had got the analysis of its glassy fibres from Mr. Pearsall. Depending on the accuracy of Dr. Gray, many authors referred to the species under this latter name; and further, for some time after the discovery of the Setubal species by Prof. Barboza du Bocage, this species, now known as *H. lusitanicum*, passed as the same species as *H. mirabile* = *H. sieboldii*. Even from the details given by Prof. Schulze, this seems clear; but in the description of Bocage's species (p. 225) no synonymic list is given, and not only does the before-mentioned fact not appear, but we find *H. lusitanicum* placed among those species "the upper end of which was not sufficiently preserved for deciding the question whether there is a sieve-plate or not." It is added that "neither on this specimen (the one figured in the Proc. Zool. Soc. Lond.) nor on others which Bocage afterwards obtained from the same locality could any portion of the sponge body be detected." But on p. 186 we find it stated that *H. lusitanicum* had been dredged from a depth of 480 fathoms south-west of Setubal, "bearing a sponge body with several oscular openings"; and again on the same page that among the Hyalonema found off the coast of Portugal by Barboza du Bocage and others, and named *H. mirabile*, there was one specimen

with an oval cup-shaped body about 8 inches in length and 4 inches in breadth, with a sieve-net on the upper truncated surface of the sponge body, extending evenly over the oscular opening and over the layer of the "spiculate cruciform spicules" in the net beams. We may further add that there were to be found in the Museum at Lisbon nearly a dozen specimens of Hyalonema which were taken at Setubal. "Most of them were preserved in spirits of wine; they were certainly the very finest collection of this remarkable Sponge in Europe. The largest had a stem about 18 inches in height; there were no parasites of any kind on it, and it was furnished with a sponge mass some 8 inches in diameter, and nearly as much in height. A second specimen was very curious, for here two apparently distinct individuals had become matted together: the two glass ropes were interlaced, and the two sponge masses had grown together" (Proc. Dublin Nat. Hist. Soc., vol. v., 1869). It would have been most important to have had the opinion of such an authority as Prof. Schulze as to whether all these specimens from Setubal are referable to Bocage's species; and whether, as we venture to think, Marshall's *H. thomsoni* may not be only a well-marked variety thereof. It is possible that by thus calling attention to the subject we may yet learn more of the treasures of the Museum of Lisbon, and nothing in these remarks can in the very slightest degree detract from the merits and importance of this splendid contribution to our knowledge of the vitreous Sponges. E. P. W.

THE FERN-ALLIES.

Hand-book of the Fern-Allies: A Synopsis of the Genera and Species of the Natural Orders Equisetaceæ, Lycopodiaceæ, Selaginellaceæ, Rhizocarpeæ. By J. G. Baker, F.R.S., F.L.S., First-Assistant in the Herbarium of the Royal Gardens, Kew. (London: George Bell and Sons, York Street, Covent Garden, 1887.)

AS the author states in the preface, "The present Handbook is planned upon the same lines as Hooker and Baker's 'Synopsis Filicum,' and the two, taken in connection, cover the whole series of the Vascular Cryptogamia." The total number of species described in the "Hand-book" is 566, and as we may now place the number of known ferns at about 3000, the fern-allies may be taken to represent about one-seventh of the recent Vascular Cryptogams. The fern-allies include only eleven genera, and about four-fifths of the species belong to the two genera *Selaginella* (335 species) and *Lycopodium* (94 species). The eleven genera are placed by Mr. Baker in four "natural orders," while the Filices form a fifth: three of these, Filices, Equisetaceæ, and Lycopodiaceæ, being isosporous; and two, Selaginellaceæ and Rhizocarpeæ, being heterosporous. In this way the relationship of the Rhizocarpeæ to the ferns is quite lost sight of; the Selaginellas and Lycopods are separated more widely than is desirable, and no place is left for the fossil heterosporous Equisetinæ. The arrangement adopted by Mr. Baker is very good for herbarium work; but for classificatory purposes it ignores certain palæontological facts which we cannot at the present day afford to overlook. Mr. Baker, however, does not deal with the fossil types, and now that we have such a complete account of the recent forms, let us hope that before long we may have as complete a synopsis of the fossil forms; a work which would be of the greatest interest and importance.

In regard to the geographical distribution of the fern-allies it is interesting to notice that *Equisetum*, *Isoëtes*, and *Pilularia* predominate in the North Temperate Zone. *Lycopodium*, *Psilotum*, *Selaginella*, *Salvinia*, and *Marsilea* are eminently tropical; and *Phylloglossum* is peculiar to the South Temperate Zone. Like the ferns, the fern-allies are best developed in the Tropics; and in the Tropics we also find the greatest number of peculiar species. Thus, out of the 566 species, 484 are met with in the Tropics of the Old and New World; and no less than 402, or 83 per cent., of these are peculiar to the Tropics. As with the ferns so also with the fern-allies, tropical America is richest in species, including 237 species, of which 212 are peculiar. The Southern Temperate Zone yields only 83 species, of which 42, or 51 per cent., are peculiar, the fern-allies being thus much less numerous than the ferns in the southern flora. In the North Temperate Zone 150 species are met with, and of these 48, or 32 per cent., are peculiar. The North Temperate Zone is thus, like the South, deficient in fern-allies as compared with ferns, and this is apparently due to the small number of fern-allies as yet reported from temperate Asia. Only 6 species occur in the Frigid Zone, and, like the ferns, represent about 1 per cent. of the whole, none of the species being peculiar.

It is difficult to realize the amount of labour and research that must have been spent upon the production of this book; but anyone who has attempted to study the genus *Selaginella* will appreciate the masterly manner in which Mr. Baker has dealt with the 335 species of the genus, more than one-fourth of which he has himself described for the first time. Most of the species of Selaginellaceæ and Rhizocarpeæ have been described by Mr. Baker in his papers on the subject which have appeared from time to time, since 1883, in the *Journal of Botany*, but several new species are described in "Fern-Allies" for the first time, recent additions to the rich treasures of Kew. It is to be regretted that Mr. Baker does not more particularly refer to his papers in the *Journal of Botany*, and it is hard to understand why, in the descriptions of *Marsilea concinna* and *M. condensata*, he has omitted the references to the *Journal of Botany*, 1886, pp. 179 and 281 respectively. Then in transferring the matter from the *Journal of Botany* he has altogether dropped out the habitat of *Azolla nilotica*. There are also in the book not a few misprints, and a want of care is shown in numbering and lettering the sections of *Selaginella*. The index is also not quite up to the mark, as in *Marsilea*, with numerous synonyms omitted, and the misprints in *Pilularia* and *Psilotum*. As the index of the "Synopsis Filicum" was published separately as a catalogue of ferns, we may perhaps be permitted to express a hope that this index will not be so published until it is carefully revised. All that is wanting, however, is only a little more careful editing, and the few faults in no way detract from the sterling value of the work.

As the only modern synopsis of the group, it is a work that must be in the hands of every botanist who deals with the Vascular Cryptogams, and it will be a lasting monument to Mr. Baker's critical accuracy and great power of dealing with a difficult set of plants. W. R. McNab.

OUR BOOK SHELF.

The Sailor's Sky Interpreter. By S. R. Elson. (Calcutta : Thacker, Spink, and Co., 1879)

THIS little book, which is written in verse, is a practical storm guide, dealing especially with the October cyclones in the Bay of Bengal. Many years of experience as pilot in the dangerous waters of the bay have made the author familiar with the phenomena of the weather in this part of the world. The details convey many a hint to students of Nature, and above all to navigators interested in the very violent storms which occur periodically at the change of the monsoons, and more especially about October at the close of the summer monsoon. The concluding stanza deals with the rules for avoiding the centre of a cyclone, and on this head the advice is both good and sound, and is at the same time put in a very concise form Sailors are very familiar with rhymes for the "Rules of the Road," but we can scarcely hope that the author's verse will be similarly mastered and remembered. Probably the author himself never contemplated such a use of his work ; but yet there are couplets and triplets of Admiral FitzRoy's which have lived for a quarter of a century, and are still valuable aids. In the last volume of the "Indian Meteorological Memoirs" full credit is given to Mr. Elson for his valuable observations on the False Point cyclone, and especial mention is made of the high value of his observations bearing on the movement of the clouds. The author possesses just that local knowledge which in a recent issue of the "Fishery Barometer Manual" the Meteorological Office lamented the want of among its observers around our coasts for the further perfecting of our "Weather Forecasts ;" and in the twenty stanzas which he has written he has pithily handed down his experiences for the benefit of his fellow-sailors.

Austral Africa. By John Mackenzie. Two Vols. (London : Sampson Low, 1887.)

THIS work, written by one who understands his subject thoroughly, ought to be cordially welcomed by all who have given any attention to the questions which have caused, during the last few years, so much trouble in South Africa. Mr. Mackenzie is convinced that these questions are not nearly so complicated and difficult as they are generally believed to be, and he has taken great pains to expound clearly and forcibly the policy which, in his opinion, would open up new markets for our commerce in South Africa, and secure the highest and best interests of the natives. The book is addressed rather to politicians than to persons interested in science, but students of the early forms of social institutions will find some statements worthy of their attention in Mr. Mackenzie's account of those native tribes with which he himself has come into contact. Archæologists will be interested, too, in what he has to say about the remarkable stone structures which are found over an extensive district to the east and north-east of Shoshong. These buildings, in the neighbourhood of which are the remains of ancient gold-mines, he compares with Persian towers of refuge and with the ancient round towers of Ireland and Britain.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

Medical Education at Oxford.

THE problem, how far the older Universities should undertake special training for the professions, is fast finding its own solution. A degree is no longer any evidence that its possessor has been through any course of wide general culture preparatory to his technical education. Recent legislation, both at Oxford and Cambridge, has all tended in the direction of enabling the undergraduate to specialize at the earliest possible point in his career. Whether advisable or not, some such movement seemed inevitable if, in the midst of the daily increasing pressure of competition, the Universities were to retain any hold on the educational development of the country. Even Prof. Freeman's articles in the *Contemporary Review* are marked by a tone of querulous despair, rather than by any hope that the tide of innovation may be checked. For knowledge as a luxury or an ornament there is neither leisure nor inclination. Cambridge was the first to yield ; but the multitudinous statutes which are every day promulgated at Oxford prove that the latter University is eagerly hurrying along the same path. New schools, new Boards of Faculties have been established ; old restrictions have been removed Large sums of money have been expended on new buildings, in which new professors may give instruction in arts and sciences unheard of by the last generation. All this has been done in order that the student may proceed as speedily as possible to those special researches which are to arm him for the battle of life.

The ordinary curriculum at Oxford is now so modified and subdivided that a Bachelor of Arts may have no more extensive general education than that smattering of school-boy knowledge required for the examination called Responsions. It is hardly realized by those who are chiefly responsible for this movement how much the whole life of the University must be altered by so radical a change in its methods and its aims. The statute-book, indeed, is in such a state of chaos that there are few, even among the officials, who can unravel the intricacies of any one Faculty. In the department of medicine an attempt has recently been made, in a pamphlet issued by the Clarendon Press, to afford concise and accurate information to the hitherto bewildered undergraduate. By means of this publication it is possible to trace out the curriculum of an Oxford medical student and to contrast the present with the older system of education. Responsions, or some equivalent test, can be passed while the candidate is still at school, and at the same time he can take an extra subject which will exempt him from the First Public Examination. After reaching the University, only an elementary pass examination in divinity will stand between him and his scientific work He may then give himself up to preparation for one of the Honour Schools of natural science. For this he will have to pass various "preliminaries," for which there are schedules of alarming proportions. Physiology and chemistry are suggested as the most suitable schools, as by their means exemption is gained from portions of the First M.B. Whichever he may select, two years of the most severe application are necessary in order to gain a satisfactory position in the Class List. He will then, in his third or fourth year, be enabled to take his B.A. degree. The study of human anatomy will next absorb his energies. The amplest opportunities are now afforded to those who desire to take up this subject while residing at Oxford. The ideal candidate depicted in this pamphlet is supposed to spend but one academical year in this department. Extraordinary, indeed, must be the powers of the teacher who could impart, and of the pupil who could receive, a sufficiently deep impression of so important a science in so brief a time. After the first examination for the M.B., residence in Oxford would come to an end, and the student would migrate probably to London. With everything in his favour he might be able to obtain his degree in six or seven years from the date of his matriculation. There are other ways in which the course of study might be arranged, but the details are of small consequence. It matters little to the public whether the degree can be obtained in five years or seven. In either case the professional acquirements will be above the average. The eminence of the examiners and the reputation of the University will be a sufficient guarantee that tests are applied of sufficient stringency to exclude the ignorant and incompetent. It is well, however, that the real state of affairs should be fairly recognized and understood by those who have been accustomed to attribute some special virtues to a University degree. It is important also to consider whether in leaving the older methods and yielding, however reluctantly, to the pressure of the hour, a retrograde step has not been taken in the history of medical education. It is always a loss when something even distantly approaching to an ideal is degraded to the level of every-day life.

The older Oxford system, if antiquated and imperfect, had

at least aims of a high and noble character—aims which could not fail to have an elevating effect on those by whom they were entertained. In former times to have taken a degree in arts, as a necessary preliminary to the beginning of a student's purely professional career, may not have meant, and, as a matter of fact, did not in the majority of cases mean, any very high standard of learning or culture. It did, however, carry with it some inestimable advantages which can never be attained under the existing system of specialization. It meant that a young man, while his mind was still plastic to all surrounding influences, was brought into contact with and joined in the same pursuits as fellow-students whose tastes would lead them to different pleasures, and whose circumstances would lead them to a variety of destinations. The physician or surgeon of the future became the companion of those who were afterwards to become clergymen, barristers, or schoolmasters. He read the same books, played the same games, belonged to the same clubs. In this way, however little actual knowledge he may have acquired, he gained an invaluable acquaintance with men's lives and habits. He formed friendships with men destined to follow very different careers. These associations could not fail to be of the greatest value to him in the pursuit of his special profession. I do not mean mere monetary advantage, but that derived from intercourse with men in other walks of life—that interchange of ideas so necessary to a healthy mind. Such a training must have been beneficial to all, but to the student of medicine it was an incalculable boon. Much of his success and much of the good he can hope to do depend on an intimate knowledge of mankind. Without that, no matter how highly trained he may be as a man of science, his acquirements will be of little avail, and his skill can never be used to the highest purpose.

How is the existing system likely to work in this direction? The student is advised and encouraged to enter at once on his special pursuits. He is to apply himself without delay to scientific study, associated with men like himself, plodding along the same track. If he aims at taking honours in natural science, he must curtail his exercise to the limits of a short "constitutional" and cut himself off from the common pleasures of the cricket-field and the river. His very social gatherings tend to consist more and more exclusively of men working in his own department. The Union and other such Clubs are given up for scientific Societies, where he thinks he can combine business with amusement. Such a life can hardly fail to narrow the most sympathetic mind, to hamper and confine the most commanding intellect; it is most unlikely to turn out a practitioner of the highest and most useful type. To live in a clique where priggishness is fostered by the worst kind of mutual admiration is hardly the ideal of University education. Fortunately the curriculum indicated in the pamphlet to which I have referred is not compulsory, and an intending medical student might not be altogether unwise if he decided to pass the first three years of his career in the ordinary pursuits of the University before turning his attention to more technical studies. Even the delay of a year or two would be more than counterbalanced to some by the benefits which such a course would undoubtedly confer.

Oxford. GEORGE I. WILSON.

Migration of Swallows along the Southern Coast.

THE following notes were made by me during a short stay at Lulworth, twelve miles east of Weymouth, from September 16 to 26. They may be of interest to some of your readers, as I have not been able to find the facts I observed recorded in any work on British birds.

When I arrived at Lulworth on the 16th, swallows and house-martins were about, but in no great numbers. On the 19th, in the course of a walk, I observed a few swallows apparently moving eastwards; and this caused me to spend the next morning on the top of a high and narrow ridge of down (Bindon Hill), running parallel with the sea—an admirable position for observation, as the movements of all birds were discernible from it at a long distance. The wind was east-north-east, and the air cold and very clear.

In half-an-hour it became clear to me that a general migration of swallows and martins was taking place along the coast in an easterly direction. The air would be thick with birds over my head for two or three minutes; then for a considerable interval hardly a bird would be visible. An ordinary glance at these dense parties was not enough to prove that they were travelling, or to show in which direction they were going; but by keeping the eye steadily upon them for some little time, and bringing the field-glass to bear on them when the eye failed, it became obvious that they were going east at a steady rate of speed, and apparently following the long spine of chalk down on which I stood, which extends from near Weymouth as far as Poole Harbour. The migration on this large scale lasted during the whole of that morning; in the afternoon the parties did not seem so large.

The next day (the 21st) a strong east wind was blowing, and the birds were not travelling high in air, but creeping steadily along the flanks of the down, and on the lower ground north and south of it. They were continually tacking, but every individual that I followed with my glass was moving swiftly towards the east. Those that were on the southern or seaward side of the down would come upon the sea at one point where the coast turns sharply northwards for a short distance: they did not attempt, however, to leave the land, but turned northwards with the coast, and pursued their way along the heights. On the 22nd and 23rd the same thing went on, but the numbers of the birds seemed to diminish, and they no longer went in parties that were plainly discernible. All this time there were a very few stationary swallows in one or two warm corners by the seaside.

From Dorset I went to Devonshire on the 26th. At Crediton and at Bideford (both warm and sheltered towns), I did not see a dozen swallows or martins in the course of a week; but I learnt that they had gathered for departure a few days before. I have since been informed that the gatherings had been noticed in Cornwall in the first week of the month. I infer that the migration I saw at Lulworth was that of the extreme West of England birds, who were proceeding along the coast to the point at which they cross the Channel. I should be glad to know where that point is.

I had reason to believe that one or two other species were moving up regularly in the same direction. The well-known migration of the pied wagtail was apparently over; but the large number of gray wagtails in a district almost destitute of water was very striking, and, as far as I could see, these also were passing eastwards. But I hope to make further observations next year.

I may add that, on returning to my home in Oxfordshire in the first week of October, I found swallows and martins passing over my village in parties during the earlier hours of each day; but, owing to the want of a convenient elevated position for watching, it was much more difficult to follow their movements than it had been at Lulworth. W. WARDE FOWLER.

Swifts.

THOUGH I cannot add anything to the interesting and valuable evidence given by your correspondent, in your last issue, with regard to swifts remaining on the wing during the dark hours of a summer night, it reminds me of a most beautiful exhibition of their flight which I witnessed at Moscow this last summer. It was on August 2, as the last rays of the setting sun were lighting up the domes and cupolas of that wonderful city, which we gazed upon from the heights of the Kremlin for the first time, that we noticed hundreds of these birds wheeling round their summits or darting hither and thither in every direction. At the same time the matchless Russian bells were pealing forth from every bell-tower in honour of the Empress's birthday, which was to be celebrated on the morrow, and it was surely difficult to believe that the swifts were not revelling in the music like ourselves, especially as I cannot remember ever seeing them again in such numbers, though our visit to Moscow was prolonged for ten days, and we frequently visited the Kremlin at the same hour. E. BROWN.

Further Barton, Cirencester, October 29.

Hughes's Induction Balance.

THE points noted by Mr. Cook on page 605 (vol. xxxvi.), are merely the well-known facts that a magnetic body has most effect when presented to the coils end-ways, *i.e.* with its greatest dimension along their axis, whereas a substance which acts mainly by conduction has most effect when presented flat-ways, or parallel to their face. Any possible effect due to diamagnetism is far too small to be thus easily noticed. OLIVER J. LODGE.

The Ffynnon Beuno and Cae Gwyn Caves.

I THINK it would be well for geologists and anthropologists to allow the age of the deposits and stone instruments found at these caves to remain an open question for the present. At present I have had no opportunity of seeing any papers on the subject, and I know of no opinions other than the one expressed by Dr. Hicks, NATURE, vol. xxxvi. p. 599. I am however fairly well acquainted with the glacial deposits of North Wales and with Palæolithic implements, and I have seen the caves and the tools found at and in them. My quite unbiased opinion is and will so remain,—unless I get very convincing proof to the contrary,—that the drift at the caves has been without doubt relaid; and is no more a true glacial deposit than the valley gravels of the Thames. As for the tools—one in the British Museum (South Kensington), and one in Denbighshire—they belong to the *very latest* of Palæolithic times, and might be passed for Neolithic; the Denbighshire example seen by me is a knife-flake with fine secondary chipping up one edge.

Dunstable. WORTHINGTON G. SMITH.

SYNTHESIS OF GLUCOSE.

ANOTHER important acquisition to our store of knowledge has recently been made. Glucose, commonly called grape-sugar, has been artificially prepared by Drs. Emil Fischer and Julius Tafel in the chemical laboratory of the University of Würzburg. This happy achievement, which is announced in the number of the *Berichte* just received, is one which has long been looked forward to, and which cannot fail to give deep satisfaction in chemical circles all over the world. As is generally the case in syntheses of this description, not only has the sugar itself been actually prepared, but, what is at least quite as important, considerable light has been thrown upon that much-discussed question—the constitution of sugars. A most remarkable, and yet only to be expected, attribute of this artificial sugar is that it is found to be entirely incapable of rotating a beam of polarized light. As is well known, there are several naturally-occurring varieties of glucose, all of which may be expressed by the same empirical constitution $C_6H_{12}O_6$, and all possessing the power of rotating the plane of polarization: dextrose, or grape-sugar, the best-known of these varieties, as its name implies deviates the plane of polarization to the right, as do several other less important varieties; while lævulose, or fruit-sugar, rotates the plane to the left. But in artificially preparing a glucose of the composition $C_6H_{12}O_6$ there is just as much tendency for one kind to be formed as another, and the probability is that both dextro and lævo are simultaneously formed, and thus neutralize each other, producing a totally inactive mixture. It may be that, as in the case of racemic acid, the two kinds are formed side by side and neutralize each other in the solution; or it may even be that, as is the case with truly inactive tartaric acid, there is a true neutralization within the molecule itself; which of these hypotheses is correct is a question for further work to decide.

The substance employed as the base of operations was acroleïn, $CH_2{=}CH{-}CHO$, the aldehyde derived by oxidation of allyl alcohol. The acroleïn was first converted to its dibromide, $CH_2Br \cdot CHBr \cdot CHO$, which was then treated with cold baryta water, whereupon the bromine was removed by the barium leaving the artificial sugar in solution. The real difficulty was found to be in the isolation of the sugar, but this was eventually overcome by the use of phenyl hydrazine, $C_6H_5 \cdot NH \cdot NH_2$, which forms a hydrazine compound of the formula $C_{18}H_{22}N_4O_4$ with the new sugar, very similar to the compounds formed by phenyl hydrazine with ordinary dextrose and lævulose. This phenyl hydrazine compound was then found to yield by reduction a base $C_6H_{13}NO_5$, which, on treatment with nitrous acid, parted with its nitrogen and left a syrupy substance, possessing all the properties of sugars, and distinguished only from ordinary grape-sugar by its optical inactivity.

The actual operations were performed briefly as follows:—

Seventy-five grammes of pure crystallized barium hydrate were dissolved in a little over a litre of water, and 50 grammes of previously redistilled acroleïn dibromide added drop by drop, the flask being continuously agitated, surrounded by ice-cold water, for about an hour. In a similar manner eight successive quantities were treated until in all about 400 grammes of acroleïn dibromide had been converted into sugar. These eight separate portions were then mixed, slightly acidified with sulphuric acid, and the barium precipitated with a solution of sodium sulphate. After removal of all the barium by filtration the solution was neutralized with soda and evaporated down to 1½ litres. On cooling, a solution of 50 grammes of the hydrochloride of phenyl hydrazine and 50 grammes of crystallized sodium acetate in 100 cubic centimetres of water were added; after standing twelve hours a reddish-brown resin separated out and was removed by filtration. 150 grammes more of phenyl hydrazine hydrochloride and the same quantity of sodium acetate were then added, and the solution warmed upon a water-bath; after again standing some time the solution became turbid, and in course of four hours a dark-coloured precipitate, partly crystalline and partly resinous, separated out. After washing and drying, and subsequent agitation with ether and trituration with alcohol to remove organic impurities, and extraction of the inorganic salts by hot water, the phenyl hydrazine compound was finally isolated.

Analysis of the recrystallized compound indicates that its composition is $C_{18}H_{22}N_4O_4$, and its properties are very similar to those of the phenyl hydrazine compound of ordinary grape-sugar, the melting-points of the two bodies being identical, 205° C. It is almost insoluble in water, ether, and benzene, and only with difficulty soluble in hot alcohol; it is more soluble in glacial acetic acid, but the solution soon becomes dark red. It crystallizes from hot alcohol in pretty little prism aggregates, while the ordinary grape-sugar compound crystallizes in spherical aggregates of fine needles. It is further distinguished from the latter compound inasmuch as a layer 20 cubic centimetres thick, is without action upon a beam of polarized light.

When reduced by means of zinc dust and acetic acid, a base was produced analogous to the one formed by the reduction of the corresponding phenyl hydrazine compound of grape-sugar. This base was difficult to isolate, owing to the non-crystallizable nature of its acetate; the fact was fortunately discovered, however, that its oxalate was crystalline, and readily obtained pure. Hence its analysis has been effected, and the numbers found point to the composition $(C_6H_{13}NO_5)_2 \cdot C_2H_2O_4$. This base reduces Fehling's solution strongly on warming, and with phenyl hydrazine regenerates the parent compound; but, once again, is optically inactive.

Finally, by the action of nitrous acid, nitrogen at once began to be evolved, and when the evolution ceased the liquid was neutralized with soda, evaporated *in vacuo*, and the residue extracted with alcohol. On evaporation of the alcohol the sugar was left as a bright brown syrup, free from nitrogen and ash, of sweet taste, and capable of instantly reducing Fehling's solution.

Up to the present time two hypotheses as to the constitution of sugars have pretty evenly balanced each other. According to one, sugars are considered, in virtue of their power of reducing ammoniacal silver solutions, as aldehydes containing also alcohol groups; on these lines grape-sugar would be formulated, $CH_2OH{-}(CHOH)_4{-}CHO$. But it has since been shown that the property of reducing ammoniacal silver solutions is not confined to aldehydes, for the series of bodies known as ketone alcohols also possess it; hence grape-sugar may also be written $CH_2OH{-}(CHOH)_3{-}CO{-}$.

CH_2OH. Both theories account for most of the hitherto known reactions of the glucoses, hence the matter has remained an open question. Drs. Fischer and Tafel, however, consider that their synthesis from acroleïn, which is itself an aldehyde, points to the probability of the former hypothesis being the correct one. The action of baryta water upon the dibromide evidently causes a simple exchange of bromine for hydroxyl, and the first product of the reaction is almost as certainly glycerine aldehyde, $CH_2OH—CHOH—CHO$. This latter substance, however, appears to polymerize at once under the influence of the baryta water into sugar, two molecules of glycerine aldehyde uniting to form a molecule of glucose.

In consideration of the fact of its derivation from acroleïn, the name acrose has been applied to the sugar which has been, with so much skill and steady determination, synthetically formed and isolated; and there can be no doubt that this name will stand as a memento of the progress made in organic chemistry during the year 1887.

A. E. TUTTON.

MODERN VIEWS OF ELECTRICITY.[1]

PART II.—CURRENT ELECTRICITY (*continued*).

IV.

Electrical Inertia.

RETURNING now to the general case of conduction, without regard to the special manner of it, we must notice that, if a current of electricity is anything of the nature of a material flow, there would probably be a certain amount of inertia connected with it, so that to start a current with a finite force would take a little time; and the stoppage of a current would also have either to be gradual or else violent. It is well known that if water is stagnant in a pipe it cannot be quite suddenly set in motion; and again, if it be in motion, it can only be suddenly stopped by the exercise of very considerable force, which jars and sometimes bursts the pipe. This impetus of running water is utilized in the water-ram. It must naturally occur, therefore, to ask whether any analogous phenomena are experienced with electricity; and the answer is, they certainly are. A current does not start instantaneously: it takes a certain time—often very short—to rise to its full strength; and when started it tends to persist, so that if its circuit be suddenly broken, it refuses to stop quite suddenly, and bursts through the introduced insulating partition with violence and heat. It is this ram or impetus of the electric current which causes the spark seen on breaking a circuit; and the more sudden the breakage the more violent is the spark apt to be.

The two effects—the delay at making circuit, and the momentum at breaking circuit—used to be called "extra-current" effects, but they are now more commonly spoken of as manifestations of "self-induction."

We shall understand them better directly; meanwhile they appear to be direct consequences of the inertia of electricity; and certainly if electricity *were* a fluid possessing inertia it would behave to a superficial observer just in this way.

But if an electric current really possessed inertia, as a stream of water does, it would exhibit itself not only by these effects but also mechanically. A conducting coil delicately suspended might experience a rotary kick every time a current was started or stopped in it; and if a steady current were maintained in such a coil it should behave like a top or gyrostat, and resist any force tending to deflect its plane.

Clerk Maxwell has carefully looked for this latter form of momentum effect, and found none. One may say, in fact, that nothing like momentum has yet been observed in an electric current by any *mechanical* mode of examination. A coil or whirl of electricity does not behave in the least like a top.

Does this prove that a current has no momentum? By no means necessarily so. It might be taken as suggesting that an electric current consists really of two equal flows in contrary directions, so that mechanically they neutralize one another completely, while electrically—*i.e.* in the phenomena of self-induction or extra-current—they add their effects. Or it may mean merely that the momentum is too minute to be so observed. Or, again, the whole thing—the appearance of inertia in some experiments and the absence of it in others—may have to be explained in some altogether less simple manner, to which we will proceed to lead up.

Condition of the Medium near a Circuit.

So far we have considered the flow of electricity as a phenomenon occurring solely inside conductors; just as the flow of water is a phenomenon occurring solely inside pipes. But a number of remarkable facts are known which completely negative this view of the matter. Something is no doubt passing along conductors when a current flows, but the disturbance is not *confined* to the conductor; on the contrary, it spreads more or less through all surrounding space.

The facts which prove this have necessarily no hydraulic analogue but must be treated *suorum generum*, and they are as follows:—

(1) A compass needle anywhere near an electric current is permanently deflected so long as the current lasts.

(2) Two electric currents attract or repel one another, according as they are in the same or opposite directions.

(3) A circuit in which a current is flowing tends to enlarge itself so as to inclose the greatest possible area.

(4) A circuit conveying a current in a magnetic field tends either to enlarge or to shrink or to turn half round according to the aspect it presents to the field.

(5) Conductors in the neighbourhood of an electric circuit experience momentary electric disturbances every time the current is started or stopped or varied in strength.

(6) The same thing happens even with a steady current if the distance between it and a conductor is made to vary.

(7) The effects of self-induction, or extra-currents, can be almost abolished by twisting the covered wire conveying the current closely on itself, or even by laying the direct and return wire side by side; whereas they may be intensified by making the circuit inclose a large area, more by coiling it up tightly into close coil, and still more by putting a piece of iron inside the coil so formed.

Nothing like any of these effects is observable with currents of water; and they prove that the phenomena of the current, so far from being confined to the wire, spread out into space and affect bodies at a considerable distance.

Nearly all this class of phenomena were discovered by Ampère and by Faraday, and were called by the latter "current-induction." According to his view the dielectric medium round a conducting circuit is strained, and subject to stresses, just as is the same medium round an electrically charged body. The one is called an electrostatic strain, the other an electro-magnetic or electro-kinetic strain.

But whereas electrostatic phenomena occur *solely* in the medium—conductors being mere breaks in it, interrupters of its continuity, at whose surface charge-effects occur but whose substance is completely screened from disturbance—that is not the case with electro-kinetic phenomena. It would be just as erroneous to conceive electro-kinetic phenomena as occurring solely in the insulating medium as it would be to think of them as occurring solely in the conducting wires. The fact is, they occur in

[1] Continued from vol. xxxvi. p. 585.

both—not only at the surface of the wires like electrostatic effects, but all through their substance. This is proved by the fact that conductivity increases in simple proportion with sectional area; it is also proved by every part of a conductor getting hot; and it is further proved in the case of liquids by their decomposition.

But the equally manifest facts of current attraction and current induction prove that the effect of the current is felt throughout the surrounding medium as well, and that its intensity depends on the nature of that medium; we are thus wholly prevented from ascribing the phenomenon of self-induction or extra-current to simple and straightforward inertia of electricity in a wire like that of water in a pipe.

We are thus brought face to face with another suggestion to account for these effects, viz. this: Since the molecules of a dielectric are inseparably connected with electricity, and move with it, it is possible that electricity itself has no inertia at all, but that the inertia of the atoms of the displaced dielectric confer upon it the appearance of inertia. Certainly they do sometimes confer upon it this appearance, as we see in the oscillatory discharge of a Leyden jar. For a displaced thing to overshoot its mean position and oscillate till it has expended all its energy, is a proceeding eminently characteristic of inertia; and so, perhaps, the phenomena of self-induction are similarly, though not so simply, explicable.

Further consideration of this difficult part of the subject is however best postponed to Part III.

Energy of the Current.

I have now called attention to the fact that the whole region surrounding a circuit is a field of force in which many of the most important properties of the current (the magnetic, to wit) manifest themselves. But directly we begin thus to attend to the whole space, and not only to the wires and battery, a very curious question arises. Are we to regard the current in a conductor as propelled by some sort of end-thrust, like water or air driven through a pipe by a piston or a fan, or are we to think of it as propelled by side forces, a sort of lateral drag, like water driven along a trough by a blast of air or by the vanes of paddle-wheels dipping into it? Or, again, referring to the cord models, Figs. 5, 6, and 13, were we right in picturing the driving force of the battery as located and applied where shown in the diagrams, or ought we to have schemed some method for communicating the power of the battery by means of belts or other mechanism to a great number of points of the circuit?

Prof. Poynting has shown that, on the principles developed by Maxwell, the latter of these alternatives, though apparently the more complicated, is the true one; and he has calculated the actual paths by which the energy is transmitted from the battery to the various points of a circuit, for certain cases.

We must learn, then, to distinguish between the flow of *electricity* and the flow of electric *energy*: they do not occur along the same paths. Hydraulic analogies, at least hydraulic analogies of a simple kind, break down here. When hydraulic power or steam power is conveyed along pipes, the fluid and its energy travel together. Work is done at one end of the tube in forcing in more water, and this is propagated along the tube and reappears at the distant end as the work of the piston. But in electricity it is not so. Electric energy is not to be regarded as pumped in at one end of a conducting wire, and as exuding in equal quantities at the other. The *electricity* does indeed travel thus—whatever the travel of electricity may ultimately be found to mean—but the energy does not. The battery emits its energy, not to the wire direct, but to the surrounding medium; this is disturbed and strained, and propagates the strain on from point to point till it reaches the wire and is dissipated. This, Prof. Poynting would say, is the function of the wire: it is to dissipate the energy crowding into it from the medium, which else would take up a static state of strain and cease to transmit any more. It is by the continuous dissipation of the medium's energy into heat that continuous propagation is rendered possible.

The energy of a dynamo does not therefore travel to a distant motor through the wires, but through the air. The energy of an Atlantic cable battery does not travel to America through the wire strands, but through the insulating sheath. This is a singular and apparently paradoxical view, yet it appears to be well founded.

Think of a tram-car drawn by an underground rope, like those in the streets of Chicago or Hampstead Hill. A contact piece of iron protrudes from the bottom of the car and grips the moving rope, which is thus enabled to propel the car. How does the energy of the distant stationary engine reach the car? *Viâ* the rope and the iron connector, undoubtedly. They both have to be strong, and are liable to be broken by the transmitted stress.

Next, think of an electric tram-car driven by means of a current taken up from an underground conductor, like that of Mr. Holroyd Smith at Manchester, or at the late Inventions Exhibition. A contact piece of wire rope protrudes from the bottom of the car and drags a little truck along the conductor, which is thus enabled to supply electricity to the electro-magnetic motor geared to the wheels. How does the energy of the distant dynamo reach the car in this case? *Not viâ* the wire connector; not even *viâ* the underground conductor. It travels from the distant dynamo through the general insulating medium between cable and earth, some little enters the conductor and is dissipated, but the great bulk flows on and converges upon the motor in the car, which is thus propelled. All the energy of the conducting wire is dissipated and lost as heat: it is the energy of the insulating medium which is really transmitted and utilized.

Phenomena peculiar to a Starting, or Stopping, or Varying Current.

There is a remarkable fact concerning electric currents of varying strength, which has been lately brought into prominence by the experimental skill of Prof. Hughes, viz. that a current does not start or stop equally and simultaneously at all points in the section of a conductor, but starts at the outside first. This fact is naturally more noticeable with thick wires than with thin, and it is especially marked in *iron* wires, for reasons which in Part III. will become apparent; but the general cause of it in ordinary copper wires can very easily be perceived in the light of the views of Prof. Poynting just mentioned.

For, remember that a current in a wire is not pushed along by a force applied at its end, so as to be driven over obstacles by its own momentum combined with a *vis a tergo*; but it is urged along at every point of its course by a force just sufficient to make it overcome the resistance there, and no more, the force being applied to it through the medium of the dielectric in which the wire is immersed. A lateral force it is which propels the electricity; and it naturally acts first on the outer layers of the wire or rod, only acting on the interior portions through the medium of the outside.

To illustrate this matter further, rotate a common tumbler of liquid steadily for some time and watch the liquid; dusting powder perhaps over it to make it more visible. You will see first the outer layer begin to participate in the motion, and then the next, and then the next, and so on, until at length the whole is in rotation. Stop the tumbler, and the liquid also begins gradually to stop by a converse process.

If the liquid sticks together pretty well, like treacle, the motion spreads very rapidly: this corresponds to a

poor conductor. If the liquid be very mobile, the propagation of motion inward is slow: this corresponds to a very good conductor. If the liquid were perfectly non-viscous, it would correspond to a perfect conductor, and no motion would ever be communicated to it deeper than its extreme outer skin.

Think now of a long endless tube full of water, say the hollow circumference of a wheel, and spin it: the liquid is soon set in rotation, especially if the tube be narrow or the liquid viscous; but it is set in motion by a lateral not an end force, and its outer layers start first.

Just so is it with a current starting in a metal wire. If the wire be fine, or its substance badly conducting, it all starts nearly together; but if it be made pretty thick, and of well conducting substance, its outer layers may start appreciably sooner than the interior. And if it were infinitely conducting, no more than the outer skin would ever start at all.

In actual practice the time taken for all the electricity in an ordinary wire to get into motion is excessively short—something like the thousandth of a second—so that the only way to notice the effect is to start and reverse the current many times in succession.

If the hollow-rimmed wheel above spoken of were made to oscillate rapidly, it is easy to see that only the outer layers of water in it would be moved to and fro; the innermost water would remain stationary; and accordingly it would appear as if the tube contained much less water than it really does. The virtual bore of the pipe would, in fact, for many purposes be diminished. So is it also with electricity; the sectional area of a wire to a rapidly alternating current is virtually lessened so far as its conducting power is concerned; and accordingly its apparent resistance is slightly higher for alternating than for steady currents. The effect is however too small to notice in practice except with thick wires and very rapid alternations.

By splitting up the conductor into a bundle of insulated wires, thus affording the dielectric access to a considerable surface of conductor, the force is applied much more thoroughly, and so the effect spoken of is greatly lessened. The same thing is achieved by rolling out the conducting-rod into a flat thin bar. Making the conductor hollow instead of solid offers no particular advantage, because no energy travels *viâ* the hollow space, it still arrives only from the outside; *unless*, indeed, the return part of the circuit is taken along the axis of the hollow like a telegraph cable. In this last arrangement all the energy travels *viâ* the dielectric between the two conductors, and none travels outside at all. It will be perceived therefore that, as in static electricity, the term "outside" must be used with circumspection: it really means that side of a conductor which faces the opposite conductor across a certain thickness of dielectric.

We learn from all this that, whereas in the case of steady currents the sectional area and material of a conductor are all that need be attended to, the case is different when one has to deal with rapidly alternating currents, such as occur in a telephone, or, again, such as are apt to occur in a Leyden-jar discharge (see Part I., p. 560), or in lightning.

In all these cases it is well to make the conductor expose considerable surface to the propelling medium—the dielectric—else will great portions of it be useless.

Hence, a lightning-conductor should not be a round rod, but a flat strip, or a strand of wires, with the strands as well separated as convenient: and though I have not yet mentioned the special effect of iron, I may as well say here that iron is about 90,000 times worse than copper for the purpose of a lightning-conductor in respect of the phenomenon just described, seven times as bad on account of its inferior conducting power, and about twice as good as copper because of its higher melting-point and specific heat.

The Question of Electrical Momentum again.

We are now able to return to the important question whether an electric current has any momentum or not, as it would have if it were a flow of material liquid. Referring to Part I. (p. 533), a hint will be found that the laws of flow of a current in conductors—the shape of the stream-lines, in fact—are such as indicate no inertia, or else no friction. Now Ohm's law shows that at any rate *friction* is not absent from a current flowing through a metal; hence it would appear at first sight as if *inertia* must be absent.

The stream-lines bear upon the question in the following kind of way. If an obstacle is interposed in the path of a current of water, the motion of the water is unsymmetrical before and behind the obstacle. The

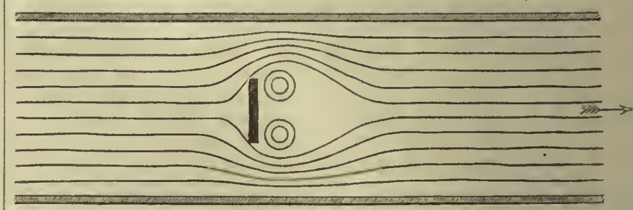

FIG. 14.—Stream-lines of water flowing through a pipe with an obstruction in it.

stream-lines spread out as the water reaches the obstacle, and then curl round it, leaving a space full of eddies in its wake (Fig. 14).

But if one puts an obstacle in the path of an electric current—say by cutting a slit in a conducting strip of tinfoil—the stream-lines on either side of it are quite symmetrical, thus—

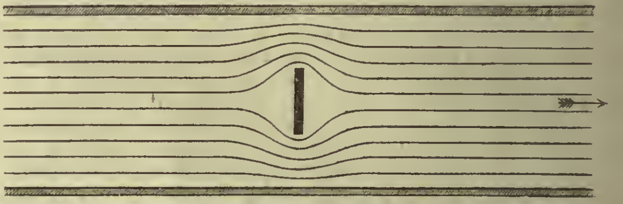

FIG. 15.—Electrical stream-lines past an obstacle.

And this is exactly what would be true for water also, if only it were devoid either of friction or of inertia, or of both.

Is not this fact conclusive, then? Does it not prove the absence of momentum in electricity?

Plainly the answer must depend on whether there is any other possible mode of accounting for this kind of flow. And there is.

For suppose that water, instead of being urged by something not located at or near the obstacle—instead of being left to its own impetus to curl round or shoot past as it pleases—suppose it were propelled by a force acting at every point of its journey, a force just able to drive it at any point against the friction existing at that point and no more; then the flow of water would take place according to the electrical stream-lines shown in Fig. 15.

An illustration of such a case is ready to hand. Take a spade-shaped piece of copper wire or sheet, heat it a little, and fix it in quiescent smoky air; looking along it through a magnifier in a strong light you will see the warmed air streaming past the metal according to the stream-lines of Fig. 15; and this just because the moving force has its location at the metal surface, and not in some region below it. (See Lord Rayleigh, NATURE, vol. xxviii. p. 139). One cannot indeed say that it is propelled at every

point of its course, but it is propelled at the critical points where the special friction occurs, and this comes to sufficiently the same thing.

We learn, therefore, that stream-lines like Fig. 15 prove one of three things, not one of two; and the three things are: (1) that the fluid has no friction; or (2) that it has no inertia; or (3) that it is propelled at every point of its course.

If any one of these is true of electricity, there is no need to assume either of the others in order to explain the actual manner of its flow. Now we have just seen that, according to Prof. Poynting's interpretation of Maxwell's theory, the third of the above is true—electricity is propelled at every point of its course; consequently, as said in Part I. (p. 533), the question of its inertia so far remains completely open.

Voltaic Battery.

Leaving this singular mode of regarding the subject for the present, to return to it perhaps after Part III., let us proceed to ask how it comes about that a common battery or a thermopile is able to produce a current.

If we allow ourselves to assume the existence of an unexplained chemical attraction between the atoms of different substances, an explanation of the action of an ordinary battery cell is easy. You have first the liquid containing, let us say, hydrogen and oxygen atoms, free or potentially free—that is, either actually dissociated or so frequently interchanging at random from molecule to molecule that the direction of their motion may be guided by a feeble directive force. Each of these atoms in the free state possesses a charge of electricity—the hydrogen all a certain amount of positive electricity, the oxygen twice that amount of negative. Into this liquid you then plunge a couple of metals which attract these atoms differently: for instance, zinc and copper, which both attract oxygen, but zinc more than copper; or, better, zinc and platinum, the latter of which hardly attracts it at all; or, better still, zinc and peroxide of lead, one of which attracts oxygen, the other hydrogen.

Immediately, the free oxygen atoms begin moving up to the zinc, the free hydrogen atoms to the other plate.

When one speaks of the plates attracting the atoms, it is not necessary to think of their exerting a force on all those in the liquid, distant and near: all that is necessary is to assume a force acting on those which come within what is called "molecular range" of its surface—a distance extremely minute, and believed to be about the ten-millionth part of a millimetre. If the zinc plate removes and combines with all the oxygen atoms which come within this range, they will be speedily replaced by others from the next more distant layer by diffusion, and these again by others, and so on. And thus there will be a gradual procession of oxygen atoms all through the liquid towards the zinc, the rate of the procession being regulated by the force acting, and by the rate of diffusion possible in the particular liquid used. All the atoms which reach the zinc neutralize a certain portion of its electricity by means of the positive charge they carry, and thus very soon it would become positively electrified enough to neutralize its attractive power on the similarly charged oxygen atoms, and everything would stop. But if a channel for the escape of its electricity be provided by leading a wire from it to the copper plate, the circuit is completed, the electricity streams back by the wire, and the procession goes steadily on. The electricity thus imparted to the copper, or platinum, neutralizes any repulsion it exerted on the negatively charged hydrogen atoms, and makes them in a similar way begin a procession towards it, deliver up their charges to it, combine with each other, and escape as gas.

Without going into all the niceties possible, this mode of thinking of the matter at least calls attention to some of the more salient features of a battery.

If, instead of two different plates, plates of the *same* metal be immersed, they will need to be oppositely electrified by some means before they are able to cause the two opposite processions, and so maintain a current in the liquid. This plainly corresponds to a voltameter.

Taking advantage of the known fact that the atoms are charged, Helmholtz avoids the necessity for postulating any chemical (non-electrical) force between zinc and oxygen, by imagining that all substances have a specific attraction for electricity itself, and that zinc exceeds copper and the other common metals in this respect.

He would thus think of the zinc attracting, not the oxygen itself, but its electric charge; and so would liken a battery cell still more completely to a voltameter. The polarization or opposition force acting at the hydrogen-evolving plate he would account for by the attraction of hydrogen for negative electricity, and the consequent repugnance of the hydrogen atoms to part with their charges.

Thermo-electric Pile.

A thermopile may be thought of in the following way, but in trying to understand the nature of these actions at present one must admit that some speculation and vagueness exist.

We have seen that when electricity is propelled through or among the molecules of a metal it experiences a certain resistance or opposition force which is exactly proportional to the speed of its motion. In other words, there is a connexion between matter and electricity in many respects analogous to fluid friction but varying accurately as the first power of the relative velocity. Hence, if an atom of matter be vibrating about a fixed point, it will tend to drive electricity to and fro with it; but if it be only one of a multitude, all quivering in different phases, they will none of them achieve any propulsion. This may be considered the state of an ordinary warm solid. But if from any cause a set of atoms could be made to move faster in one direction than in the reverse direction—to move forwards quickly and backwards slowly—then such an unsymmetrically-moving set *will* exert a propulsive tendency and tend to drive a current of electricity forwards, simply because the force exerted is proportional to the velocity, and so is greater on the forward journey than on the return.

Wherever conduction of heat is going on along a substance the atoms are in this condition. They are driven forward infinitesimally quicker, by the more rapidly moving atoms at the hot end, than they are driven back by the less rapidly moving atoms in front. And hence such a slope of temperature exerts a propulsive tendency: there is an electromotive force in a substance unequally heated.

This fact was discovered theoretically and verified experimentally by Sir William Thomson.

But not only is there such a force at a junction of a hot and cold substance, there is also a force at the junction of two substances of different kinds, even though the temperature be uniform. It is not quite so easy to explain how it now comes about that the atoms at this kind of junction are moving faster one way than the other; nevertheless, such a thing is not unlikely, considering the state of constraint and accommodation which must necessarily exist at the boundary surface of two different media. However it be caused, there is certainly an E.M.F. at such a junction.

Thus, then, in a simple circuit of two metals, with their junctions at different temperatures, there are altogether four electromotive forces—one in each metal, from hot to cold or *vice versâ*, and one at each junction; and the current which flows round such a circuit is propelled by the resultant of these four.

But the contact force at a junction is by no means confined to metals. It occurs between insulators also, and it is to it that the striking effects produced by all frictional electric machines are due.

By thus noticing that the connexion between matter and electricity, known as resistance and defined by Ohm's law, is competent to produce contact electromotive forces, we may perceive how it comes to pass that in good conductors such forces are so weak, while in insulators they are so strong. Electricity slips through the fingers of a metal as it were, and the driving force it can exert is very feeble; while an insulator gets a good grip and thrusts it along with violence.

The metals differ in their gripping power, and, roughly speaking, the best conductor makes the worst thermo-electric substance. A bad conductor, like antimony, or, still better, galena, or selenium, or tellurium, makes a far more effective thermo-electric element than a well-conducting metal. Not that specific resistance is all that has to be considered in the matter; there is also a specific relation between each metal and the two kinds of electricity. Thus, iron is a metal whose atoms have a better grip of positive than of negative electricity, and so a positive current gets propelled in iron from hot to cold. Copper, on the other hand, acts similarly on negative electricity, and it is a negative current which is driven from hot to cold in copper. And all the metals can be classed with one or other of these two, except perhaps lead, which appears to grip both equally, and so to exert no differential effect upon either.

Passage of Electricity through a Gas.

There remains to be said something about the way in which electricity can be conveyed by *gases*.

The first thing to notice is that there is no true conduction through either gases or vapours; in other words, a substance in this condition seems to behave as a perfect insulator—perhaps the only perfect insulator there is. Not even mercury vapour is found to conduct in the least. This shows that mere bombardment of molecules, such as is known to go on in gases, is not sufficient either to remove or to impart any electric charge.

The commonest way in which electricity makes its way through a gas, setting aside the mere mechanical conveyance by solid carrier, is that of disruptive discharge. Let us try and look into the manner of this a little more closely, if possible.

First of all, since locomotion is possible to the molecules of a gas the same as of any other fluid, it is natural to ask why electrolysis does not go on as in a liquid. Now, for electrolysis in a liquid two conditions seemed necessary: first, that the atoms or radicles in a molecule should be oppositely charged with electricity; second, that they should be in such a condition (whether by dissociation or otherwise) that interchanges of atoms from molecule to molecule, or, in some other way, a procession of atoms, could be directed in a given direction by a very feeble or infinitesimal force.

Since a gas does *not* act as an electrolyte, one of these conditions, or perhaps both, must fail. Either the atoms of a gas-molecule are not charged, which is a plausible hypothesis for elementary gases, or else the atoms belonging to a gas-molecule remain individually belonging to it, and are not readily passed on from one to another.

When one says that a gas does not act as a common electrolyte, the experimental grounds of the statement are that a finite electrostatic stress certainly is possible in its interior—a stress of very considerable amount; and when this stress does overstep the mark and cause the electrode to yield, the yielding is evidently not a quiet and steady glide or procession, but a violent breaking down and collapse, due to insufficient tenacity of something. One may therefore picture the molecules of a gas, between two opposite electrodes or discharge terminals maintained at some great difference of potential, as arranged in a set of parallel chains from one to the other, and strained nearly up to the verge of being torn asunder. In making this picture one need not suppose any fixture of individual molecules: there may be a wind blowing between the plates; but all molecules as they come into the field must experience the stress, and be relieved as they pass out.

If the applied slope of potential overstep a certain limit, fixed by observation at something like 33,000 volts per linear centimetre for common air, the molecules give way, the atoms with their charges rush across to the plates, and discharge has occurred. The number of atoms thus torn free and made able to convey a charge by locomotion is so great that there has never been found any difficulty in conveying any amount of electricity by their means. In other words, *during* discharge the gas becomes a conductor, and, being a conductor by reason of locomotion of atoms, it may be called an electrolytic conductor.

But whether the charge then possessed by each carrier atom intrinsically belonged to it all the time, or whether it was conferred upon the components of the molecules during the strain and the disruption, is a point not yet decided.

What is called "the dielectric strength" of a gas—that is, the strain it can bear without suffering disruption and becoming for the instant a conductor—depends partly on the nature of the gas, and very largely on its pressure. Roughly, one may say that a gas at high pressure is very strong, a gas, at low pressure very weak. An ordinary electrolyte might be called a dielectric of zero strength.

One reason why pressure affects the dielectric tenacity of a gas readily occurs to one: it is certainly not the only one, but it can hardly help being at least partially a *vera causa;* and that is, the fact that in a rare gas there are fewer molecules between the plates to share the strain between them.

Thus if 40,000 volts per centimetre break down ordinary air, 40 volts per centimetre ought to be enough to effect discharge through air at a pressure of about $\frac{3}{4}$ millimetre of mercury; and at a pressure of 50 atmospheres 2,000,000 volts per centimetre should be needed.[1]

A Current regarded as a Moving Charge.

To review the ground we have covered so far. We first tried to get some conception of the nature of electrostatic charge, and the function of a dielectric medium in static electricity. We next proceeded to see how far the phenomena of current electricity could be explained by reference to electrostatics. For a current, being merely electricity in locomotion, need consist of nothing but a charged body borne rapidly along.

Charge a sphere with either positive or negative electricity, and throw it in some direction: this constitutes a positive or a negative current in that direction. There is nothing necessarily more occult than that. And a continuous current between two bodies may be kept up by having a lot of pith balls, or dust particles, oscillating from one to the other, and so carrying positive electricity one way, and negative the other way. But such carriers, as they pass each other with their opposite charges, would be very apt to cling together and combine. They might be torn asunder again electrically, or they might be knocked asunder by collision with others. Unless they were one or other, the current would shortly have to cease, and nothing but a polarized medium would result.

Instead of pith balls, picture charged atoms as so acting, and we have a rough image of what is going on in an electrolyte on the one hand, and a dielectric on the other. The behaviour of metals and solid conductors is more obscure. Locomotive carriage is not to be thought of in them; but, inasmuch as no new phenomenon appears in their case, it is natural to try and

[1] It is true that tension per unit area, or energy per unit volume, is proportional to the *square* of the potential-slope, and I attach no special importance to the simple proportion assumed in the text. There is a great deal more to be said on these subjects, but this is scarcely the proper place to say it.

picture the process as one not wholly dissimilar; and this is what in one place we tried to do; with, however, but poor success.

I have said that an electric current need be nothing more occult than is a charged sphere moving rapidly; and a good deal has been made out concerning currents by minutely discussing all that happens in such a case. But, even so, the problem is far from being a simple one. One has to consider not only the obviously moving charge, but also the opposite induced charge tied to it by lines of force (or tubes of induction, as they are sometimes called), and we have this whole complicated system in motion. And the effect of this motion is to set up a new phenomenon in the medium altogether—a spinning kind of motion that would not naturally have been expected; whereby two similarly charged spheres in motion repel one another less than when stationary, and may even begin to attract, if moving fast enough; whereby also a relation arises between electricity and magnetism, and the moving charged body deflects a compass needle. Of which more in the next Part. OLIVER J. LODGE.

(*To be continued.*)

THE TWEEDDALE COLLECTION.

THE great collection of birds formed by the late Marquess of Tweeddale has now safely arrived in London, and has been deposited in the Natural History Museum at South Kensington. It is sufficient to say that it equals in extent the valuable donation of American birds presented by Mr. Osbert Salvin and Mr. F. Du Cane Godman, numbering about 27,000 specimens; and though inferior in number of individual skins to the great Hume collection, which reached the phenomenal number of 63,000 specimens, it is not inferior in interest to either of these wonderful collections. Mr. Hume thoroughly worked the territory of the British Asian Empire from Scinde to Assam and Manipur, from Khatmandu to Ceylon, and from Tenasserim to Singapore; but to the eastward of these countries the work had been continued by other naturalists, and the results of their labours are largely represented in the Tweeddale collection, which now forms part of the British Museum.

On the death of the late Marquess, his entire collection and library were bequeathed by him to his nephew, Capt. R. G. Wardlaw Ramsay, of Whitehill, a naturalist of high promise and performance; and in the moment of satisfaction at receiving his magnificent donation one cannot help feeling great regret that the many cares and duties incident upon his succession to the family estates at Whitehill have temporarily deprived him of the leisure necessary for the working out of the great collection left to him by his uncle. The facilities for ornithological study, however, at the Natural History Museum, are now rapidly becoming so perfect that one may reasonably hope that he will, in common with all ornithologists, be able to work in that institution with the same comfort as in his own museum in Scotland. If in future years the student of birds finds that at South Kensington the work he loves can be done more expeditiously and with command of a larger series of specimens than in any other Museum in the world, his gratitude will be largely due to the four naturalists we have mentioned—Mr. Allan Hume, Messrs. O. Salvin and F. D. Godman, and Capt. Wardlaw Ramsay—for the unexampled generosity which has led them to present to the British nation the wonderful collections which will make our Ornithological Museum famous for all time.

Many naturalists who read this article will remember how, twelve years ago, the entire collection of bird-skins in the British Museum was contained in a few book-cases in a dingy cellar at Bloomsbury, where all the skins were kept in wooden boxes—a barbarous method, which was not only clumsy, but actually harmful to the specimens themselves. The development of the collection since that era is one which any English naturalist may consider with pride. Not only is the invaluable series of skins in the British Museum now well cared for and properly housed, but the *raison d'être* of the large collections in private hands has been removed. It is admitted on all sides that had the facilities of study in the old days been such as they now are in the Natural History Museum, there would have been no need for ornithologists to devote their private means to the formation of the collections which have, however, now become the foundation of the greatest Ornithological Museum in the whole world.

The three great collections which have enriched the British Museum during the last two years have each been, in their way, of supreme importance for zoological science. The Hume collection was a perfect marvel in the way of complete series of specimens. Not only are the various plumages of the Indian birds exemplified in a manner hitherto unheard of, but even the geographical ranges of most of the species are illustrated in a perfect way by the series of specimens contained in the collection. The Salvin-Godman donation consisted of American birds, and added hundreds of species to the British Museum which were desiderata to that collection. Though not so rich in series of various plumages as the Hume collection, the number of gaps in the quota of American birds which their donation filled was simply enormous, and from being one of the most backward in regard to its neotropical collection of birds, the British Museum is now one of the foremost as regards the value of its American series.

The Tweeddale collection "takes up the running," so to speak, where Mr. Hume left off, and it must not be supposed that the donation now made by Capt. Wardlaw Ramsay is merely the collection of skins left to him by his uncle. To imagine this would be but a poor appreciation of the energy which has led him during the last few years to develop and greatly increase the collection by the addition of a large number of birds obtained during his military career in the East, and by hundreds of other valuable specimens acquired since his uncle's death. Thus the skins from the Kurrum Valley in Afghanistan, and from the Karen Hills in Burmah, obtained by Capt. Ramsay himself, are supplementary additions of the highest value to the Hume collection, inasmuch as Mr. Hume never had correspondents in these parts, and the specimens from the Andamans and Nicobars are also of great importance; but of course the interest of the Tweeddale collection centres round the expedition to the Philippine Archipelago made by Mr. Alfred Everett for the late Marquess. Mr. Everett visited several islands on which no zoologist had previously trod, and as a natural result he discovered some beautiful new species of birds which are still unrepresented in any other collection but that of Capt. Ramsay. Altogether Mr. Everett furnished material for twelve important memoirs by the Marquess of Tweeddale, and the number of Philippine types now presented to the British Museum adds immensely to the wealth of the donation. Lord Tweeddale was also greatly interested in an obscure family of birds—the Drongos, or Crow-shrikes (*Dicruridæ*)—and possessed a wonderful collection of these birds, although it may be stated that there is scarcely a family of Oriental birds which is not strongly and completely represented in the collection.

Ornithologists will understand the nature of this noble gift of Capt. Ramsay when they learn that in addition to the collection of birds he has also presented the whole of the splendid Tweeddale library (nearly 3000 volumes) to the British Museum, to be placed in the Bird-Room, alongside of the collection of skins, for the benefit of students of ornithology. The Tweeddale library is one of the best in the world, containing many rare volumes which

we have not seen elsewhere, and this donation alone is worth several thousands of pounds. With a series of bird-skins now numbering nearly a quarter of a million, and with the best ornithological library in the world, it will be strange if the work done at the British Museum in future be not rendered an easy and an enjoyable task, though it must be remembered that the very magnitude of the collection contributes to the difficulty of its exact study. The writer may be excused an expression of deep gratitude to the ornithologists who have enriched the collection under his charge, so that from a series of (at the most) 40,000 skins, the number of bird-skins has been raised in fifteen years to more than 200,000, and he merely adds a hope that he may see the British Museum become the repository of all the work of English ornithologists, not only from this country, but from all parts of the Empire.

This article has dealt merely with the three great donations which have been received during the last two years, and has not recorded the many other collections, of almost equal importance, which have been acquired by the Trustees of the British Museum since 1872, the results of the life-work of such naturalists as Sclater, Wallace, Gould, and others of whom the country is proud, the acquisition of whose collections also is a source of the greatest encouragement to the writer.

R. BOWDLER SHARPE.

THE STORM OF OCTOBER 30.

THE gale which swept over the southern part of England on the morning of Sunday the 30th was both sudden and severe. On the previous day the weather was exceptionally fine over the country generally, and in many places it was a truly "pet" day. The Meteorological Office, in their morning report referring to the barometric rise which was going on in the south and west, remarked that "some improvement in the weather is therefore likely in the south." In the afternoon of Saturday, however, there were signs of approaching bad weather, and by six o'clock a disturbance was shown to be situated off Scilly, the barometer reading 29·4 inches. The Meteorological Office considered the situation sufficiently menacing for the issue of storm signals, and the south cone was hoisted in the south and south-west districts. During the night the storm passed in an east-north-east direction over the southern counties of England, travelling at the rate of about thirty miles an hour. The centre passed almost directly over London at about five o'clock in the morning, when the wind changed suddenly about 180°, the barometer at the time registering 28·86 inches, and in the next two hours the mercury rose 0·4 of an inch. At Greenwich Observatory the anemometer recorded 17·2 lbs on the square foot at 7·5 a.m., which is equivalent to an hourly velocity of about sixty miles. By 8 a.m. the centre of the disturbance had passed to the eastward of our islands and was situated a short distance off Yarmouth. The storm afterwards travelled in a north-easterly direction, maintaining somewhat its former rate of movement, and on Monday morning the central area was in the neighbourhood of Stockholm. The gale was rather severe on our southern coasts, but its principal violence was felt in the English Channel and on the French and Danish coasts. The Paris *Bulletin* shows that at many of the stations the wind reached the full force of a hurricane, and the sea was terrific. The amount of rain which fell during the storm was unusually heavy, 1·59 inches being registered at Scilly, and upwards of an inch at other stations in the south of England and also in the north of France. As is commonly the case with these quick-travelling and rapidly-developing storms, the disturbance was a "secondary" to a larger disturbance which was passing from off the Atlantic to the northward of our islands.

ROBERT HUNT, F.R.S.

MR. ROBERT HUNT, whose death we have already briefly announced, was born at Devonport, then called Plymouth Dock, on September 6, 1807. His father was a naval officer who perished, with all the crew, in H.M.S. *Moucheron*, in the Grecian Archipelago. Robert Hunt, left to his mother's care, was destined for the medical profession; and, having been placed with a surgeon in London, he attended the anatomical lectures of Joshua Brooks; but his studies were interrupted by failing health, and his medical training was never completed. In 1840, Mr. Hunt became secretary to the Royal Cornwall Polytechnic Society at Falmouth. His earliest contributions to science were in connection with photography—a subject to which he applied himself with assiduity immediately on the announcement of Daguerre's discovery in 1839. Mr. Hunt's investigations led to the discovery of several new processes, which were either described in the *Philosophical Magazine* or announced to the British Association. His experimental researches on the chemical activity of the highly refrangible rays of the solar spectrum, his work with the actinograph, and his study of the influence of light upon the germination of seeds and the growth of plants, formed the subject of numerous papers between 1840 and 1854. Mr. Hunt's "Researches on Light" appeared in 1844. His "Manual of Photography," which was the first general work on the subject published in this country, passed through six editions.

While Mr. Hunt was in Cornwall he undertook some interesting inquiries, conjointly with the late Mr. Robert Were Fox, into the electrical phenomena of mineral veins; and he also entered upon an examination of the air in some of the Cornish mines. In 1845 he came to London, at the invitation of Sir H. T. De la Beche, to succeed Mr. Thomas Jordan, as Keeper of Mining Records at the Museum of Economic Geology, then recently established in Craig's Court. On the establishment of the Government School of Mines in 1851, he was appointed Lecturer on Mechanical Science, and opened his course with an address on the importance of cultivating habits of observation. After holding this position for two sessions he resigned it to the late Prof. Willis, and undertook for a short time the duties of Lecturer on Physics. In 1854 Mr. Hunt was elected a Fellow of the Royal Society.

For the last thirty years Mr. Hunt's energies have been mainly directed to the collection and collation of statistical information relating to British mining and metallurgy. From 1853 until the abolition of the Keepership of Mining Records he published regularly the annual volumes of "Mineral Statistics," containing a vast mass of voluntary returns obtained by his personal influence. As a member of the Royal Coal Commission of 1866, he undertook the statistical part of the inquiry, and published detailed information on the coal resources of the country.

The technical education of the metal-mining population of the West of England was a subject that Mr. Hunt always had at heart. He was an earnest advocate for the establishment of local mining schools, and should be regarded practically as the founder of the Miners' Association of Cornwall and Devon—a body now amalgamated with the Mining Institute. In 1883, Mr. Hunt published a voluminous work on "British Mining." After the death of Dr. Ure he consented to edit the "Dictionary of Arts," and brought out successively the fifth (1860), sixth (1867), and seventh (1875) editions of this work. At the same time Mr. Hunt possessed great literary taste, which found scope in several lighter works, such as his "Poetry of Science," "Panthea, or the Spirit of Nature," and the "Romances of the West of England." Mr. Hunt's long, busy, and useful life was closed on the 17th ult. His remains were interred in Brompton Cemetery.

NOTES.

THE vacancy in the representation of Cambridge University, caused by the death of Mr. Beresford Hope, raises again the question of the desirability that the Universities should be represented in Parliament by men of distinguished culture, whether literary or scientific. Men of science will be glad to hear that a movement is on foot in Cambridge to induce the President of the Royal Society to allow himself to be nominated as a candidate for the membership of the University. A meeting will be held on Saturday for the purpose of considering the question of the representative. It is believed that Prof. Stokes, if he finds the feeling to be strong in favour of his acceptance, will regard it as his duty to place his services at the disposal of the electors. A more distinguished representative never offered himself for the suffrages of any University in this country. His presence in the House of Commons would be another pledge that questions involving the interests of science would be discussed with adequate knowledge in that assembly.

IN presenting the prizes to the successful students of the Bath Lane Science and Art School at Newcastle-on-Tyne, Lord Randolph Churchill expressed the opinion that when "the State has laid the foundation by freely contributing to elementary education, localities ought to come in and ought to build on that foundation whatever edifice may be necessary for the further and higher technical education of the artisan." "This school," he continued, "is essentially the result of pure local effort, pure local energy, and pure local pride. You have, I understand, carried on the whole work of this school without the smallest assistance from Government of any sort or kind. Now, I was saying that technical education is supposed to be a great requirement of the present day, and I was using the illustration of your school to show that localities can if they wish, if they have the energy and the determination, supply that technical education for themselves." In a letter to the *Times* a writer signing himself "Y." has exposed the ignorance displayed by Lord Randolph Churchill in this astonishing statement. The Newcastle school, instead of being carried on simply by means of "local effort," has been largely aided by the Government. As "Y." points out, the last Report of the Science and Art Department shows that in 1886 the payments on results made to the school were for science £1212 10*s*., and for art £238 10*s*., while the students' fees for instruction in science were £1228, and in art £150. It is discreditable that a man in Lord Randolph Churchill's position should be capable of making such a mistake s this. The incident is important, for it indicates the spirit in which too many of those who talk wildly about "economy" approach the consideration of the grave question as to the duty of the State with regard to education. Lord Randolph Churchill has been Chancellor of the Exchequer, and may some day be Chancellor of the Exchequer again. With his crude notions and inaccurate information, the injury he might do in this position to our educational system is simply incalculable.

THE College of State Medicine, lately incorporated, ought to be a remarkably successful institution, if we may judge from the names of its officers. The Chairman of Council is Sir Joseph Fayrer, K.C.S.I., F.R.S. The following are the members of the Council:—Sir John Watt Reid, K.C.B., Sir Thomas Crawford, K.C.B., Sir William Guyer Hunter, K.C.M.G., M.P., Sir Henry Roscoe, F.R.S., Sir Douglas Maclagan, Surgeon-General William Robert Cornish, C.I.E., Richard Quain, F.R.S., Edward Klein, F.R.S., Robert Brudenell Carter, and Arthur Trehern Norton. The following are *ex-officio* members:—The President of the Sanitary Institute, the President of the Society of Medical Officers of Health, the President of the Public Health Medical Society, the Professor of Public Health to the College. Mr. James Cantlie is the honorary secretary.

THE first Congress of the Dutch Society of Naturalists lately met at Amsterdam under the presidency of Dr. Stoknis, who delivered an address on nationality and natural science. Among the other addresses were the following: on Martinus of Marum, who made a large electric machine at the end of the last century, by Prof. Bosscha (Delft); and on the education of future naturalists, by Prof. Spruyt (Amsterdam).

AN Exhibition of Textile Goods and Machinery will be held at Warsaw about the middle of December next. It will be open to all countries.

THE expedition which the Finnish Archæological Society despatched to the Upper Yenisei last summer, to prosecute archæological researches in that locality, has just returned to Helsingfors. It has brought back drawings of about thirty stone figures, and copies of a large number of inscriptions, hitherto not deciphered, on a rock, on nine raised stone slabs, and on many stones along the upper course of the Yenisei. The expedition has also gathered a vast collection of objects belonging to the Siberian Bronze Age.

IN his latest Annual Report, Mr. Putnam, Curator of the Peabody Museum of American Archæology and Ethnology, says that during the past year several large collections of special interest have been added to the Museum. The most important is the Bucklin collection from ancient graves in Peru, principally at Ancon. This collection is particularly rich in textiles and in ornaments and implements made of silver and bronze; and among the objects in pottery there are many new forms and styles of ornamentation. Another collection of over 300 specimens of pottery obtained from the province of Piura, Peru, has also been purchased, and nearly every vessel adds some important feature to the already instructive Peruvian collection in the Museum. A third collection consists of 337 pottery vessels, a number of whistles and other objects made of pottery, 245 stone implements, and several large carved stones, some circular, and others resembling animals, supposed by some archæologists to be seats, and by others to be metates. This collection has been catalogued and placed in the exhibition cases with the other objects from the ancient graves in Chiriqui. It was obtained from the well-known collector of antiquities in Chiriqui, Mr. J. A. McNiel, who has resided in the State of Panama for many years. Mr. Putnam expresses much regret that Mr. McNiel has not been able to keep together the contents of each grave. He is dependent on the sale of the specimens for the means to carry on his work, so that many of the objects he obtained are now widely scattered, and archæologists have no means of tracing the development of the arts of the people, which could have been done had the collection been kept together and the associations of every object carefully noted.

WE have received the Proceedings of the U.S. National Museum during the year 1886. This is the ninth volume of the series. It contains many interesting and valuable papers, some by members of the scientific corps of the National Museum, others by writers who have made portions of the collections of the Museum subjects of special study. The volume opens with a list of fishes collected in Arkansas, the Indian Territory, and Texas, in September 1884, with notes and descriptions, by Mr. D. S. Jordan and Mr. C. H. Gilbert. Among the other papers are: notes on fulgurites, by Mr. G. P. Merrill; a review of Japanese birds, by Mr. L. Stejneger; a catalogue of animals collected by the Geographical and Exploring Commission of the Republic of Mexico, by Mr. F. Ferrari-Perez; a description of six new species of fishes from the Gulf of Mexico, with notes on other species, by Mr. D. S. Jordan and Mr. B. W. Evermann; and Norsk naval architecture, by Mr. G. H. Boehmer. At the end of the volume there are twenty-five plates, each accompanied by its explanation.

Some of the difficulties with which the curator of a museum in tropical climates has to contend are described in the last report on the Colombo Museum. Mr. Haly states that naphthaline is not so powerful a protection against the effects of climate as was anticipated. It seems to prevent the attacks of mites, but it is powerless against fungus. It is hoped that it will ward off the attacks of the fish insect on the labels. As an instance of the rapidity with which this pest works, it is mentioned that one case was re-painted, and the objects rearranged and labelled. No naphthaline was procurable at the time, and in a fortnight several labels had been defaced and several numbers lost. Carbolic acid and corrosive sublimate have both been mixed with the gum, but their use is objectionable, as they discolour the labels, and do not afford permanent protection. Every object in a tropical climate, Mr. Haly says, ought to be exhibited on its own stand, and that stand labelled by hand in black or white paint. The Museum has also been attacked lately by a fungus. Not only have the specimens themselves been attacked, but the wood of the teak cases, and even the glass, has been covered. In one case the insects were absolutely rolled round and connected together by its fine filaments—filaments so fine as to be invisible through the glass. Naphthaline, benzine, cyanide of potassium, carbolic acid, and other substances have all been tried in vain: the only check to its growth was citronella oil.

The "Educational List and Directory of the United Kingdom for 1887–88" (Sampson Low), edited by Mr. William Stephen, has just been published. This is the second issue of the work. The editor's aim is to concentrate within reasonable space the names of the chief educational institutions of the Kingdom. Besides being a guide for the use of parents and guardians, and a directory for all who give attention to educational matters, the volume is interesting, as Mr. Stephen claims, on account of the fact that it is the first methodical effort to unite for practical purposes the designations of our educational institutions, from the Universities downwards, in England, Wales, Scotland, and Ireland. No "descriptive matter" has been introduced.

The Cardiff Naturalists' Society have issued a valuable descriptive list of the indigenous plants found in the neighbourhood of Cardiff, with a list of the other British and exotic species found on Cardiff Ballast Hills. The compiler is Mr. John Storrie, Curator of the Cardiff Museum.

A stalactite cave has been discovered near Steinbach in the Upper Palatinate. It can only be approached by a shaft 1 square metre in diameter and 40 metres deep. The cave is divided into several compartments, through one of which a stream of water slowly flows. The numerous stalactites are of great beauty. Another stalactite cavern, equalling the celebrated Dechen cavern, both in extent and peculiarity of form, has been discovered in the so-called Billstein, between Hirschberg and Warstein (Westphalia). The interior consists of several chambers. Numerous animal remains (probably prehistoric) have been found in the cave.

The death is announced of Herr August Kappler, whose excellent book on Dutch Guiana is well known. He died at Stuttgart, aged seventy-one.

We regret to announce the death of Dr. E. Luther, Professor of Astronomy at the Königsberg University, also Director of the Observatory. He was born February 24, 1816.

The weather in Iceland during the summer has been very unusual. The ice did not leave the north and east coast till the middle of September, or quite a month later than usual. Storms and fogs have been very frequent. The last mail brings news that the weather was then (the middle of October) dry and fine. Frost had, however, set in in several parts. This is the last news we shall have from the island until next spring.

At a recent meeting of the Wellington (New Zealand) Philosophical Society, Sir James Hector exhibited samples of trachyte tuff and breccia, constituting the auriferous deposit lately found in the level ground west of Te Aroha. The material, which appeared to be somewhat of the nature of an infiltrated quartz reef which had been decomposed and then distributed as a surface deposit, was found to contain gold at a rate varying from two ounces to fourteen ounces to the ton. The gold occurs in twisted angular flakes and grains, and is associated in a light feldspar sand with heavier grains of quartz mica and titanic iron. Sir James Hector is of opinion that it will probably prove to be the outcrop of an important reef, from which the sulphides have been removed by decomposition, so that gold is left in its free state. The gold is the usual alloy of the district—consisting of gold 80·47 per cent., silver 16·91, loss 2·62, previous assays having varied from 77 to 84 per cent.

The last number of the *Excursions et Reconnaissances* of Saigon contains an account by M. Navelle of a journey which he made in Annam from the port of Thi-Nai, commonly called Quin-hon, to Bla. The route lay through the great town of Binh-Dinh, and by the ruins of Quin-hon, at one time the capital of the Chams or Ciampois. This leads the traveller to narrate the vicissitudes of the once powerful kingdom of Ciampa, which was overthrown in the fifteenth century, after seven centuries of contest with Annam. The narrative is mainly interesting from the circumstance that the traveller visited a number of important towns hitherto unseen by Europeans. At the town of Dong-pho, he met an official who at one time performed curious functions. The Kinh-li was an Annamite official appointed to reside beyond the frontiers to organize Annamites who fled from their native country, and to direct their raids against neighbouring States. These vagabonds, thus directed, acted as the van-guards of regular Annamite invasion. M. Landes, in the same number, continues his researches into the folk-lore of the races of French Indo-China. In the present instance he gives the tales and legends of the Tjames, Chams, or Ciampois, above-mentioned. They have long been subjugated, and are now divided into two groups, one inhabiting the Bin-thuan province, the other Cambodia. Until recently they were amongst the most unknown peoples of the peninsula, but M. Aymonier's accounts of his long exploration in Binh-thuan, which were published in recent numbers of *Excursions*, have thrown much light on the subject. The stories published by M. Landes were collected from the mouth of a Cham, and are mostly fairy tales.

Dr. Karl Pettersen, Director of the Tromsö Arctic Museum, has lately written a pamphlet on the state of the drift-ice in the Arctic seas during the last few years. In this pamphlet he offers some suggestions as to the way in which attempts to reach the North Pole should be made. "It seems to me," he says, "that every year shows more and more clearly that it is a sheer waste of life and money to despatch casual and erratic expeditions to the North Pole. In my opinion the result would be attained most easily, surely, and cheaply by despatching every year, for a period of ten or eleven years, a certain number of well-equipped steamers from certain suitable spots towards the Pole. As the ice-masses in the Polar Basin are, without doubt, in a constant but varying motion, this plan would enable one or another of the expeditions to seize the right moment for a dash northward. We could not, of course, be absolutely certain of success, for experience has proved that the state of the ice in a particular locality at a particular time does not enable us to predict what it will be in the same locality in the following year. Still, the opportunity to reach a high latitude would present itself sooner or later. The expeditions of past years having almost conclusively demonstrated that it will be

impossible to reach the North Pole along the west coast of Greenland, the *point d'appui* for the journeys on the plan advocated would be confined to the European and Asiatic Polar seas. The routes I should recommend are four: viz. one along East Spitzbergen to Franz Josef Land, and northwards, starting from the north of Norway; one east of Franz Josef Land, starting from the Yenisei or Obi; one *viâ* Franz Josef Land, starting from the New Siberian Islands or the Lena; and one from a suitable spot in Behring Strait. I have every reason to believe that if four such expeditions were in readiness in these localities every year during a period of eleven years, we should by the end of that time, by one or another of the routes, have solved the problems which still face us around the Pole. Probably the scheme might be carried out most advantageously by international co-operation, as in the case of the Polar Research Expeditions of 1882–83. In any case, I venture to think that the plan of any expeditions should not be finally formed before July, or, if possible, August. By that time many of the huntsmen have returned from their first voyage to several parts of the Arctic Sea, and the expeditions would be in possession of a fair knowledge of the state of the ice in each. I believe that, should the route chosen be *viâ* Spitzbergen or Novaya Zemlya, a careful study of the weather and wind in North Norway during the spring and early summer would benefit Polar expeditions immensely, showing whether the route to the north or east of Spitzbergen should be followed, or the more eastern one by Novaya Zemlya."

THE additions to the Zoological Society's Gardens during the past week include a Grand Eclectus (*Eclectus roratus*) from Moluccas, presented by Miss P. Lockwood; a Goffin's Cockatoo (*Cacatua goffini*), habitat uncertain, presented by Miss Barton; a Water Rattlesnake (*Crotalus adamanteus*), a Water Viper (*Cenchris piscivorus*), two American Black Snakes (*Coluber constrictor*), a Chicken Snake (*Coluber quadrivittatus*), two Mocassin Snakes (*Coluber fasciatus*) from Florida, presented by the Natural History Society of Toronto; two Green Lizards (*Lacerta viridis*), twelve Spotted Salamanders (*Salamandra maculosa*), two Common Snakes (*Tropidonotus natrix*) from Italy, presented by Messrs. Paul and Sons; an Algerian Tortoise (*Testudo mauritanica*) from Algeria, deposited; an Aye-Aye (*Chiromys madagascariensis*) from Madagascar, purchased; six Painted Terrapins (*Clemmys picta*), two Corn Snakes (*Coluber guttatus*), two Milk Snakes (*Coluber eximius*), two Mocassin Snakes (*Tropidonotus fasciatus*), two Ribbon Snakes (*Tropidonotus saurita*), two Hog-nosed Snakes (*Heterodon platyrhinos*), two Grass Snakes (*Cyclophis vernalis*), six Dekay's Snakes (*Ischnognathus dekayi*), nine American Green Frogs (*Rana halecina*), ten Noisy Frogs (*Rana clamata*), a Wood Frog (*Rana sylvatica*), a Changeable Tree Frog (*Hyla versicolor*), nine Red-backed Salamanders (*Plethodon erythronotus*) from Canada, received in exchange; a Blood-breasted Pigeon (*Phlogœnas cruentata*), bred in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *NOVEMBER* 6–12.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 6

Sun rises, 7h. 4m.; souths, 11h. 43m. 44·2s.; sets, 16h. 24m.: right asc. on meridian, 14h. 45·2m.; decl. 15° 59′ S. Sidereal Time at Sunset, 19h. 26m.

Moon (at Last Quarter November 8, 17h.) rises, 19h. 50m.*; souths, 3h. 54m.; sets, 11h. 58m.: right asc. on meridian, 6h. 54·4m.; decl. 20° 14′ N.

GEOGRAPHICAL NOTES.

THE Danish Government has decided upon hydrographically measuring and charting the Guldborg Sound, the new harbour at Odense, in the Island of Funen, and the Randers and Mariager fjords in Jutland. Two vessels will also be engaged in preparing a naval chart of the coast around Denmark. It has also been decided to despatch an Expedition—the cost being estimated at £4000—to Iceland next summer, for the purpose of effecting hydrographical measurements around that island. Great fjords and waterways are here still unmeasured—a danger to navigation and a loss to science. It is believed that these researches may lead to important scientific discoveries, principally as regards zoology, meteorology, and geography. Moreover, they would probably be of great benefit to the Iceland fisheries, which are far from being thoroughly developed on account of the ignorance of existing fishing-banks, the temperature of the sea, &c. The researches, which will be similar to those carried out around Norway for some years past, will be effected with the Government schooner *Ingolf*, a vessel particularly adapted for the purpose. It is intended to employ the months of May, June, July, and August in this work, which, it is estimated, will be fully accomplished in five years.

IN the *Bollettino* of the Italian Geographical Society for September Signor E. Modigliani concludes his series of papers on Nias, with a detailed account of the physical features, natural history, and social condition of that island. The hilly surface is

relieved in some places by extensive open plains covered with tall grasses, and the forest vegetation is rapidly disappearing, owing largely to the wasteful habits of the natives. The accompanying seismic tables contain records of the earthquakes that occurred between the years 1843–86, some of which were very violent and attended by marine disturbances destructive to shipping, and driving boats and barges hundreds of yards inland. But there are no active volcanoes, and the prevailing formation appears to be a much-weathered compact limestone resting on gray or bluish Miocene marls and other argillaceous clays. The geological as well as the zoological conditions show that Nias, like the other islands running parallel to the west coast of Sumatra, must have formerly been connected with the mainland; and as Sumatra itself at one time certainly formed part of the Malay Peninsula, this chain of insular groups would appear to mark the original line of the Asiatic seaboard in this direction. Signor Modigliani's collections include 178 birds, representing 62 species, of which 8 are described as new, but allied to corresponding species in Sumatra; consequently the separation must have taken place at a very remote period—a conclusion also confirmed by other considerations. His rich zoological collection, comprising over 7000 specimens, has been presented to the Museum of Genoa.

METEOROLOGICAL NOTES.

THE Report on the Meteorology of India in 1885, being the eleventh year of the series, has just been published, and contains an immense mass of valuable information. The accumulation of Indian statistics during the last ten years may be best shown by a comparison of the following figures:—The number of stations at which the mean temperature is recorded has increased from 51 to 127, and the rainfall stations from 134 to 471. From this huge volume of 516 large quarto pages we can only note here a very few general remarks. Considerable attention is paid to solar radiation, the chief feature of which is found to be that the maximum intensity generally occurs during the winter half of the year (October to March), when the sun is in southern declination, and the thickness of the absorbing atmosphere traversed by the sun's rays is at a maximum. This is said to be apparently due to the fact that over a large part of India the atmosphere is most cloudy in the summer and autumn months. It would appear from the mean result of the sun-thermometer readings in all parts of India that the average intensity of solar heat had reached a minimum in 1884, and in 1885 underwent an appreciable increase. The duration of bright sunshine is now regularly recorded at four stations, and Mr. Blanford considers that the sunshine-recorder promises to be even more important than the sun-thermometer, since the duration of sunshine is a more direct measure of the amount of solar heat reaching the earth's surface than the registry of its mean maximum intensity. Anemometers are in use at nearly all the stations, and fourteen of them are large anemographs of the Kew pattern. The resultant direction of the winds is, however, computed by Lambert's old formula, which is based on the assumption that the force of all winds is equal, an assumption which is obviously often very misleading. The work is accompanied by maps showing the positions of the meteorological observatories and the mean distribution of temperature, pressure, and wind.

M. GARRIGOU-LAGRANGE describes, in the *Annuaire de la Société Météorologique de France*, his apparatus for registering the ascending and descending air-currents. The experimental anemometer is fixed on a mast at Limoges, and consists of four small fans moving round a vertical axis, and recording, by electrical arrangements, on a drum covered with ruled forms. The curves obtained by this method show plainly the upward or downward movement of the air, and the velocity is easily read off. The experiments show that ascending winds are generally stronger and more frequent than the descending, owing no doubt to the eddies caused by obstacles met with by the currents.

IN *Das Wetter* M. Seemann discusses the results of the storm-warnings issued by the *New York Herald* between September 1886 and January 1887, and finds that out of twelve warnings only three were quite successful, and three partially so. The wording of the telegrams is not so absolute as formerly; many of the depressions pass to the northward of our islands, and our weather is *disturbed*, although the gales do not always strike our coasts; judged in this light, the warnings may be more successful than when actual storms are predicted. On pp. 83–87 of the same journal Dr. C. Lang describes his method of predicting night-frost, from the position of the dew-point. From the Munich observations for 1879–86 he finds that 441 predictions of night-frost could be given, of which 89 per cent. were successful. In 8 per cent. of the cases, night-frost did not follow, and in 3 per cent. frost occurred unexpectedly. This method may be of considerable benefit to agriculturists; reference to this subject has been made by Mohn, Buchan, and others.

DR. GROSSMANN has published "Meteorologische Divisionstafeln" (Hammerich and Lesser, Altona), which will be very useful to meteorological observers in the calculation of monthly means, and daily means from hourly observations. For a dividend of four figures the quotient is given by simple inspections, and for more figures by interpolation by means of a table of proportional parts. The principle of construction is due to Dr. Köppen, and some of the tables were printed in *Aus dem Archiv der Deutschen Seewarte*, vol. i. 1878. Dr. Crelle's well known "Tables de Calcul" (Reimer, Berlin, 1869) are equally useful, but being in a large volume are not easily accessible to observers generally. The chief merit of Dr. Grossmann's tables lies in their publication in a form specially suitable to the wants of meteorological observers, and at the low price of about sixpence for single copies. They extend to four pages only, and are intended to be pasted on cardboard.

THE Italian Central Meteorological Office has published its *Annali* for the year 1884, in three thick folio volumes, containing a mass of meteorological, magnetical, and astronomical data. The meteorological services of Italy are very complicated, as in addition to the Central Office there are many large and independent establishments from which we possess long series of observations, some of them dating from the middle of last century. The Government established a Committee for Weather Telegraphy in 1863, under M. Matteuci, and in 1865 the Meteorological Section of the Ministry of Agriculture commenced the issue of the *Meteorologia Italiana*; from this originated the present office in 1877, located at the Collegio Romano. The service is now under the able superintendence of M. Tacchini, and includes 135 stations of the second order, some of which, *e.g.* those of Stelvio, Valdobbia, Cimone, and Etna are important mountain observatories; in addition to which there are 515 rainfall stations, and stations at the military settlements of Assab and Massowah. The work contains valuable discussions on thunderstorms, evaporation, and on the microscopical examination of atmospheric dust.

A SPECIAL meeting of the Meteorological Society of Mauritius, in honour of the Queen's Jubilee, was held on August 6, on which occasion Dr. Meldrum gave an interesting sketch of the origin and labours of the Society, and of the Royal Alfred Observatory. Charts were exhibited showing the tracks of the cyclones in the Southern Indian Ocean in each year from 1856 to 1886, also magnetograms showing simultaneous disturbances at Zi-ka-wei and Mauritius on January 9, 1886; and curves showing the apparent connection between solar, magnetical, and auroral phenomena, and also between solar phenomena and the frequency of cyclones, rainfall, and the depth of water in rivers, together with other articles of interest. Dr. Meldrum stated, with reference to the history of meteorology in the island, that a memorial was presented to the Governor in April 1851, suggesting the desirability of systematic observations, and the Meteorological Society was consequently founded on August 1 of that year. Shortly afterwards the office of Government Meteorological Observer was created, to which office Mr. Meldrum succeeded in 1862, and the two institutions, although distinct, have co-operated with each other. Regular observations were commenced at the new Observatory (see NATURE, vol. xxxvi. p. 546) in November 1874. We cannot enumerate here the many useful works which have been carried on, but the Hydrographer to the Admiralty has expressed the wish that the track charts should be published, and Mr. Meldrum has been informed that the Meteorological Council would probably publish them. He also states that tide-gauges will soon be erected at two points on the coast, and expresses a desire for the establishment of a high mountain station.

IN the *American Meteorological Journal* for September, Mr. H. Allen discusses the theory of the outflow of air under falling rain. It has been assumed by some meteorologists that the rain, drops carry with them and compress the air, which, flowing out-produces at times a considerable wind velocity (see article on

"Lightning" in Johnson's Encyclopædia). Several hypothetical cases are considered, and the author concludes that, although his computations may need some modification after further study, we can safely say that no appreciable velocity of air is produced by compression from falling rain. The same journal contains a long paper on the theory of the wind-vane by Prof. G. E. Curtis, reprinted from the *American Journal of Science* for July last. He discusses the relative stability of a straight vane, and that with a double or spread tail. The first reference to the latter is apparently in *Voigt's Magazin*, 1797, and this form has been in common use in England since about 1840. The formulæ show that for a frictionless bearing (1) that the oscillations of both vanes are smaller as the vanes are longer and larger; (2) that the spread vane is always more stable than the straight vane; and (3) that this advantage in stability is greater for long vanes than for short vanes, and is independent of the wind velocity. The author finds that, with equal friction, a spread vane is the more sensitive, and that consequently for two vanes of equal sensitiveness the spread vane will have the greater friction and will come to rest more quickly.

THE *Jahresbericht* of the Central Physical Observatory of St. Petersburg for 1885 and 1886, and the *Annalen* for the year 1885, have recently been published. The Russian system is very important, not only as being the most extensive on the globe, but on account of the great climatic contrasts and the completeness of the observations. The present Director, Dr. H. Wild, of Berne, was appointed in 1867, and under his able superintendence the number of stations has greatly increased and the quality of the observations has much improved. The central Observatory is situated about a mile from the sea, on the island of Wassili-Ostrow; the principal observing department has been transferred since 1878 to Pawlowsk, about four miles distant, and is placed under the superintendence of Dr. E. Leyst. The observations for 1885 are contained in two quarto volumes of about 700 pages altogether. In addition to the first class observatories, the number of stations of the second order amounts to 255, and of these the monthly and yearly results of 208 are published on the international scheme; from 38 of the stations the observations are published *in extenso*. Many new stations have been added recently, especially in Siberia, and in newly-acquired territories, *e.g.* Merv, Batoum, &c. One of the Siberian stations, viz. Werchojansk (lat. 67° 34′, long. 133° 51′) is stated by Dr. Köppen to be the coldest known point of the earth. The mean temperature there for the year was − 2°·9 F. The mean for January and December was − 62°·9, and the minimum in January − 88°·6 (far beyond the range of the usual tables). The mean temperature of July rose to 60°·6, and the minimum for that month was 39°·2. The number of rainfall stations for which the observations are given is 650, against 252 in the previous year; the data published are the monthly values, the maximum fall in 24 hours, and the number of days of rain and snow. A complete catalogue of the meteorological observations in Russia and Finland, by Dr. E. Leyst, giving the life-history of each station, has been published in the *Repertorium für Meteorologie* this year. This work also contains many valuable discussions of the vast amount of materials available for the purpose. The index of the *Annalen*, being mostly in Russian, is difficult to refer to.

THE WORK OF THE INTERNATIONAL CONGRESS OF GEOLOGISTS.[1]

I.

ELEVEN years ago the Association met at Buffalo. It was the year of the Centennial Exhibition, and we were honoured by the presence of a number of European geologists. This naturally opened the subject of the international relations of geology, and the proposition to institute a Congress of Geologists of the world took form in the appointment by the Association of an International Committee. The project thus initiated found favour elsewhere, and there resulted an international organization, which up to the present time has held three meetings. It was convened first at Paris in 1878, then at Bologna in 1881, and at Berlin in 1885. Its next meeting will be held in London next year, and an endeavour will be made to secure for the United States the honour of the fifth meeting. The original Committee of the Association has been continued, with some change of membership, and has sent representatives to each session of the Congress.

The work of the Congress, as originally conceived and as subsequently undertaken, has for its scope geologic nomenclature and classification, and the conventions of geologic maps. The particular classifications attempted are the establishment of the major divisions used in historic and stratigraphic geology and the subdivision of volcanic rocks. In nomenclature three things are undertaken: (1) the determination of the names of historic and stratigraphic divisions, (2) the formulation of rules for nomenclature in palæontology and mineralogy, and (3) the establishment and definition of the taxonomic terms of chronology (period, epoch, &c.) and of stratigraphy (system, series, &c.). The map conventions most discussed are colours, but all signs for the graphic indication of geologic data are considered. The Congress has also undertaken the preparation of a large map of Europe, to be printed in forty-nine sheets.

The work was for the most part planned at the Paris meeting, and Committees were appointed to formulate subjects for action by the Congress at subsequent sessions. Briefly stated, the work accomplished to the present time is as follows. Agreement has been reached as to the rank and equivalence of the taxonomic terms employed in chronology and stratigraphy, a set of rules for palæontologic nomenclature has been adopted, and many sheets of the map of Europe have been prepared for the engraver. A partial classification of stratified rocks has been agreed to, and also a partial scheme of map colours, but the reports of proceedings indicate that action in these matters is tentative rather than final.

It is understood that both of these subjects will have prominent place in the proceedings at the London meeting, and the American Committee is endeavouring to prepare itself for representative action at that meeting by ascertaining the opinions of all American geologists on the various subjects. It has asked this Section to set apart a day for the discussion of some of the more important questions, and it can hardly be doubted that the Section will realize the mutual advantage of thus assigning the time requested. I am personally so impressed with the importance of the possible work of the Congress that I shall devote the present hour also to its consideration.

The first thing the Congress did was to select names for a set of categories to express the taxonomic rank of stratigraphic divisions on the one hand, and of chronologic divisions on the other. In the terminology of zoology and botany the words kingdom, class, order, family, genus, species, and so forth, however difficult of definition they may severally be, nevertheless are used always in the same order of inclusion. No systematist in those sciences would think of grouping orders together and calling them a family, or of styling a group of families a genus. But in geology there is no such uniformity of usage. With some writers a group is larger than a series, with others it is smaller. With some an age includes several periods, with others a period includes several ages. There are even writers who ignore the distinction between stratigraphy and chronology; and among the classifications submitted to the Congress is one in which an age is subdivided into systems. There is a manifest advantage in bringing order out of this chaos, and so great is the utility of uniformity and perspicuity that the decisions of the Congress in this regard will unquestionably be followed by future authors. The terms and the order adopted by the Congress are as follows. Of stratigraphic divisions, that with the highest rank is *group*, then *system*, *series*, and *stage*. The corresponding chronologic divisions are *era*, *period*, *epoch*, and *age*. This order of rank is strange to most English readers and writers, and so is one of the terms—*stage*; but the strangeness is only a temporary disadvantage, and will not seriously retard the adoption of the convention. The fact that we have previously used the words in a different sense, or that their etymology might warrant a different meaning, need not deter us, for we know from frequent experience that the connotations of a word transferred from one use to another quickly disappear from consciousness, leaving it purely denotative. The introduction of the word *stage*, which can hardly be said to have had an English status heretofore, or at least the introduction of some new word for that part of the column, was necessitated by the restriction of the word *formation* to a special meaning—the designation of mineral masses with reference to their origin.

[1] Vice-Presidential Address read to Section E of the American Association for the Advancement of Science, August 10, 1887, by Mr. G. K. Gilbert.

The same restriction vacated another office that had been filled by formation, and to this office no appointment was made. I refer to the use of the word to denote indefinitely an aggregate of strata—as in saying, this formation should be called a series rather than a system. This is an important function, for which some provision must be made. I suggest that we may advantageously enrich our language by the permanent adoption of *terrane*, a word whose English meaning has not been well established.

The fixation of the chronologic terms creates a similar difficulty. We have crystallized out of our magma the terms *era*, *period*, *epoch*, and *age*, and there remain in the ground-mass only *eon*, *cycle*, and *time*. Of these, *eon* has a poetic connotation which seems to unfit it for this particular use; *cycle* implies repetition or recurrence; and *time* has been so generally applied to unlimited duration that it is difficult to apply it also to limited duration, even though the nature of the limitation be indefinite. On the whole, *time* seems open to the least objection, but I cannot help regretting that either *period* or *age*, both of which have heretofore passed current in the indefinite sense, was not reserved by the Congress for that function. With English-speaking peoples the word *eon* could have been better spared for the definite series.

But while the terms selected by the Congress are not beyond criticism, the benefits to be derived from an agreement in an orderly system are so great that I for one shall unhesitatingly adopt them as they stand—provided, of course, that the Congress makes no effort to improve its selection. A small reform of this nature yields its profit to this as well as future generations, and I hold it a duty to favour even those reforms which involve so much effort and pains that their blessings cannot be realized by those who initiate them. Such are the exchange of our English spelling for a rational system, and the exchange of decimal notation in arithmetic for a binary notation. My application of the new nomenclature begins with this address, in the preparation of which I have experienced its utility. That you may have no difficulty in interpreting my reformed language, I have placed the taxonomic legend on the wall, with the addition of the complementary indefinite terms—terrane and time.

Terranes.		Times.
Group.	...	Era.
System.	...	Period.
Series.	...	Epoch.
Stage.	...	Age.

There are propositions before the Congress to distinguish the names of individual groups, systems, series, and stages by means of terminations, those of the same rank having the same termination. Thus it is proposed by a Committee that every name of a group shall end in *ary*—Tertiary, Primary, Archeary; it is proposed that names of systems end in *ic*—Cretacic, Carbonic, Siluric; it is proposed that names of series end in *ian*—Eifelian, Laramian, Trentonian; and it is proposed that stage names terminate with *in*. Another Committee suggests that *ic* be used for stages instead of systems. The adoption of such a plan would enable a writer or speaker to indicate the taxonomic rank of a terrane without adding a word for that purpose. If he regarded a certain terrane taking its name from Cambria as a system, he would call it the Cambric; if he esteemed it only a series, he would say Cambrian; and there would be no need of adding the word system or series in order to express his full meaning. Conversely, the reader or hearer would always learn its taxonomic rank, or supposed rank, whenever a terrane was mentioned. These I conceive to be the advantages derivable from the change, but they would not be the only effects. It would become impossible for a geologist to name or allude to a terrane without declaring its rank, and the consequences of this would be evil in many ways. In the first place, one could not discuss terranes from any point of view without expressing an opinion as to their taxonomy, and the change would thus contravene one of the most important rights of opinion—namely, the right to reserve opinion. Again, geologists who differed as to the rank of a terrane would necessarily terminate its title differently, and a needless synonymy would thus be introduced. In the third place, the created necessity for taxonomic discrimination on all occasions would tend to direct undue attention to taxonomic problems. Taxonomy would be conceived by many geologists as an end instead of a means, just as correlation has been conceived, and energy would be wasted in taxonomic refinement and taxononomic controversy. It is convenient for purposes of description and comparison to classify the strata that constitute a local columnar section in phalanges of various magnitude or rank, but the criteria on which we depend for discrimination are in the nature of things variable, and offer ground for endless difference of opinion; and it would be extremely nnfortunate to have such differences perpetually brought to the foreground.

Another subject considered by the Congress is the nomenclature of palæontology. A Committee appointed for the purpose formulated rules for the establishment of the names of genera and species, and their report was adopted by the Congress. I have no opinion to express as to the wisdom of the rules, but it is a matter of surprise that a body of geologists assumed to speak with authority on the subject. From one point of view palæontology is a part of geology; from another point of view it is a part of biology. In so far as it names genera and species it is purely biologic, and it would seem proper that the students of fossils unite with the students of living animals and living plants in the adoption of rules of nomenclature.

A similar remark applies to the nomenclature of mineralogy, in regard to which no action has yet been taken. The most intimate relations of systematic mineralogy are with chemistry.

Yet another projected work of the Congress is the classification of eruptive rocks. Up to the present time action has been deferred, and it may reasonably be hoped that no scheme of classification will be adopted. If there existed a system of classification which gave general satisfaction and had stood the test of time, there would be little harm—and little or no advantage—in giving it the official stamp of approval. If the main features of a classification were well established and the residuary discrepancies were recognized as unessential, it is conceivable that some benefit might be derived from the submission of the matter to an assembly of specialists. But the actual case is far different. Not only is there wide difference as to the classification of volcanic rocks, but there is no agreement as to the fundamental principles on which their classification should be based, for we still lack an accepted theory of volcanism. At the same time observation is being pushed with great vigour, and with the aid of new and important methods. With the rapid growth of knowledge and ideas, classifications are continually remodelled, and the best is in danger of becoming obsolete before it has been printed and circulated. Should the Congress enter the lists, one of two things would occur. Either its classification would be treated like that of an individual, and ignored as soon as a better one was proposed; or it would be regarded as more authoritative, and new facts would for a time be warped into adjustment with it. In either case the reputation of the Congress would eventually suffer, and in one case science would suffer also.

There remain to consider the two most important undertakings of the Congress, the classification of terranes and the unification of map colours. The Congress is attacking these subjects indirectly by means of a third undertaking, the preparation of a geologic map of Europe, and this method of approach has had the effect of making it difficult properly to interpret its action. There can be no doubt that those who originally organized the work contemplated the enactment of a stratigraphic classification to be applied to the entire earth, and the selection of a colour scheme for use either in all geologic maps or in all general geologic maps. But at the Berlin session the Committee in charge of work on the map of Europe pressed the Congress for the determination of questions on which hung the completion of the map, and many hasty decisions were reached, while not a few disputed points were referred to the Map Committee. The debates indicate that much or all of this work was provisional or of merely local application, but the resolutions adopted show little qualification. It should be added that the official minutes of the meeting are still unpublished. In view of the uncertainty thus occasioned I shall not attempt to characterize the attitude of the Congress on the subject of classification, but shall merely develop my individual view.

It is the opinion of many who have discussed the general classification of terranes by convention of geologists that the smallest unit of such classification should be the stratigraphic system. What is a stratigraphic system? The Congress implies a definition in saying that a system includes more than a series and less than a group, and that the Jurassic is a system; but this gives only a meagre conception, and we need a full one. As the problem of classification demands a true conception of a system, and as there is reason to believe that a false conception is

abroad, it is proper that in seeking the true one we begin with the elements.

The surface of the land is constantly degraded by erosion, and the material removed is spread on the floor of the ocean, forming a deposit. This process has gone on from the dawn of geologic history, but the positions and boundaries of land and ocean have not remained the same. Crust movements have caused the submergence of land, and the emergence of ocean bottom, and these movements have been local and irregular, districts here and there going up while other districts went down. The emergence of ocean bottom exposes the deposit previously made on it, and subjects it to erosion. In this way every part of the known surface of the globe has been the scene of successive deposition and erosion, and in many districts the alternations of process have been numerous. It is manifestly impossible that either erosion or deposition should ever have prevailed universally, and it has been established by the study of stratigraphic breaks that a time of erosion has often interrupted deposition in one region while deposition was uninterrupted in another.

In transportation from its region of erosion to its place of deposition detritus is assorted, and it results that the simultaneous deposits on the bottom of an ocean are not everywhere the same. Equal diversity is shown in the ancient deposits constituting geologic formations. It is a general fact that synchronous formations have not everywhere the same constitution.

Many of the variations in deposits are correlated with depth of water and distance from shore, and it results that elevation and subsidence in regions of continuous deposition produce changes in the nature of the local deposit.

The animals and plants of the earth are not universally distributed, but are grouped in provinces. In the geologic past similar provinces existed, but their boundaries were different, shifting in harmony with the varying geography of the surface. From time to time the barriers separating contiguous provinces have been abolished, suffering them to coalesce; and conversely new barriers have arisen, creating new provinces. From the earliest Palæozoic to the present time the species of animals and plants have been progressively modified, the nature of the modification depending on local conditions. The faunas and floras of different provinces thus become different, and the longer the provinces remain distinct the greater is the divergence of life. The removal of a barrier either produces a new fauna by the fusion of the two previously separated, or else obliterates one and extends the area of the other. In either case there is a change toward the unification of life, and in either case there is an abrupt change in a local fauna. Thus the secular evolution of species, combined with the secular and kaleidoscopic revolution of land areas, leads to two antagonistic tendencies, one toward diversity of life on different parts of the globe, the other toward its uniformity. The tendency toward uniformity affords the basis for the correlation of terranes by comparison of fossils; the tendency toward diversity limits the possibilities of correlation.

If now we direct attention to some limited area and study its geology, we find that under the operation of these general processes it has acquired a stratigraphic constitution of a complex nature. Its successive terranes are varied in texture. Breaks in the continuity of deposition are marked by unconformities. The fossils at different horizons are different, and when they are examined in order from the lowest to the highest, the rate of change is found to vary, being in places nearly imperceptible and elsewhere abrupt. It is by means of such features as these —that is, by lithologic changes, by unconformities, and by life changes—that the stratigraphic column is classified into groups, systems, series, and stages. A system is a great terrane separated from terranes above and below by great unconformities or great life breaks, or both. Smaller unconformities, smaller life changes, and lithologic changes are used for the demarcation of series and stages; and, on the other hand, exceptionally great unconformities and life breaks are used to delimit groups. As the same criteria determine groups, systems, and series, differing only in degree, the precise definition of the term system is impossible, and in many cases the gradation of a terrane as a group, a system, or a series is largely a matter of convenience. From this point of view a system is somewhat artificial, but there is a more important sense in which it is natural. It is limited by stratigraphic or palæontologic breaks above and below, and these breaks are natural. The taxonomist is not warranted in dividing systems where no such break exists.

Transferring now our attention to some other area, distant from the first, and studying its stratigraphy, we find that the same principles enable us to divide it independently into stages, series, systems, and groups. Its fossils are not the same, but they are to a certain extent similar, and the sequence of life is approximately parallel. We cannot compare stage with stage, nor series with series perhaps, but we can compare system with system, and making the comparison we discover that the breaks are at different places. While one area was upraised and subjected for a time to erosion, the other received continuous deposition. While life in one area, enjoying constant conditions, was almost unchanged for long ages and even epochs, it was revolutionized in the other by the irruption across some obsolescent barrier of strong and aggressive faunas and floras. The systems of one area, therefore, do not coincide with the systems of the other in their beginning and ending. They may differ in number, and they may differ greatly in magnitude, and in the duration they represent. They are, in fact, a different set of systems.

The case I have described is ideal, but not false. It represents the common experience of those who have developed the geologic histories of remote districts, and attempted to correlate them with the geologic history of Europe. There does not exist a world-wide system nor a world-wide group, but every system and every group is local. The classification developed in one place is perfectly applicable only there. At a short distance away some of its beds disappear and others are introduced; further on, its stages cannot be recognized; then its series fail, and finally its systems and its groups.

If I have properly characterized stratigraphic systems—if they are both natural and local—it goes without saying that the classification of the strata of all countries in the dozen or so systems, as proposed by some of the members of the Congress, is impossible.

I hasten to add that from the point of view of these gentlemen what they advocate is not necessarily impossible, for they have a different conception of a system. They regard it not as local but as universal. It is their privilege to define their terms as they please, and we will not dispute about mere words, but I cannot too strongly or too earnestly insist that a system which is universal is artificial. It may be natural in one geologic province, but it is artificial in all others. Take for example the Jurassic. It is a natural system in Europe. In the eastern United States no strata are called Jurassic with confidence, and at the west the rocks called Jurassic merge with those called Triassic. In India, Medlicott tells us, a Jurassic fauna occurs at the summit of a great natural system containing a Permian fauna near its base. In New Zealand, according to Hutton, a continuous rock-system, dissevered by great unconformities from other systems, bears at top fossils resembling those of the lower Jurassic, and lower down fossils of Triassic facies. To establish a Jurassic system in either of these countries it is necessary to divide a natural system, and a Jurassic system thus established would be necessarily artificial.

This is the sort of classification implied by the assumption that systems are world-wide. It is not impossible, but it is highly unadvisable. It is classification for the sake of uniformity, and its uniformity is Procrustean. The natural systems of a region are the logical chapters of its geologic history. If you group its strata artificially according to the natural divisions of another region, you mask and falsify its history. The geologic history of the earth has as great local diversity as its human history. As in human history, there are inter-relations and harmonies and a universal progress, but these are perceptible only in the general view, and the student whose preconceptions lead him to exaggerate the harmonies and ignore the discrepancies perverts the meaning of every page.

I prefer, therefore, my own definition of system, making it natural and consequently local, and I earnestly oppose any attempt to coerce the geology of one country in a rigid matrix formed over and shaped by the geology of another country.

The ideas I oppose have arisen in connection with the work of correlation. Some geologists appear to regard correlation as the determination in distant localities of identities; the more philosophic regard it as the determination of the actual relations, whether they be of identity or difference. With the former the basis of correlation is the universality of geologic systems; with the latter it may be said to be the universality of geologic time.

Now in the comparative study of local geologic histories, just as in the comparative study of local human histories, it is a

matter of convenience to have a common scale of time. It is not essential, but it is highly convenient. In human history we use an astronomic scale of equal parts, designating each unit by a number. In geology no scale of equal parts is available, and we employ the eras and periods, and to some extent the epochs, of the local geologic history first deciphered—that of Europe. These time-divisions bear the same names as the groups, systems, and series of strata whose deposition occurred within them.

So far as the science of geology is concerned the selection of Europe as its first field of study was a matter of chance, and the adoption of the European time scale as a general standard may therefore be said to have been accidental. Though the local rock scheme on which it is based is natural, the time scale, considered as universal, is arbitrary. Another locality would have afforded a different scale, but its authority would neither be greater nor less. The scale being recognized as arbitrary, and a mere matter of convenience, it is legitimate to modify and fix it by formal convention. The Congress can do good service to geologic technology by putting it in the best possible shape and giving it an official status. In my judgment only a small number of divisions should be admitted, not more than the number of periods of the European scheme. In a general way the durations represented by the co-ordinate divisions should be as nearly equal as practicable, but a certain concession might be made to chronologic perspective on account of our superior opportunities for studying the later history. Some of the shorter periods might perhaps be united under new names. Each line of division between periods should be defined by means of a stratigraphic plane of division, and this can be done with precision if a locality is made part of the definition.

Especially should pains be taken to declare the arbitrary nature of the scale. Even with this precaution it will be misconstrued by many, for there is a tendency of the mind to attach undue weight to classification. Wherever we draw lines of separation, we lose to a certain extent the power to recognize continuity. When, for example, the clock strikes twelve on New Year's Eve, time seems to stop and begin again. We speak of the achievements of the nineteenth century—and despite ourselves we think of them too—as though a new industrial epoch began in A.D. 1800. And so it is easy for the beginner in geology to accept as discontinuous the eras and periods of which his text-book treats, and it is hard for him afterward to unlearn the lesson.

There is reason to believe that confusion of ideas in regard to geologic classification has been fostered by the employment of the same set of names for the divisions of the time scale and for the local terranes on which they are founded. It might be well to furnish the time scale with names suggesting times—such names as the brothers Rogers applied to the terranes of Pennsylvania; but so radical a change is hardly feasible, especially as we should thus lose the mnemonic connection of times with corresponding terranes. I propose, as a means of accomplishing the end with the least inconvenience, that a set of time words be derived from the terrane names by modifying the final syllables. The time words should all have the same termination, and that should differ from any terminations occurring in the terrane names. I suggest for the ending of time words the syllable *al*. With such a nomenclature, Jurassic and Devonian would denote only certain European rock systems, while Jural and Devonal would denote periods of the standard time scale; and we could speak of the Chico-Tejon series as partly Eocenal and partly Cretaceal without seeming to imply the existence in California of the Eocene and Cretaceous systems of Europe.

A few minutes ago I opposed the differentiation of words by terminations because it abrogated the power of indefinite expression; I now favour it for the same reason. It is well to be indefinite as to the taxonomic rank of terranes while their characters are imperfectly known, but it is not well to confuse terranes with times.

It is not to be assumed that a time scale adopted now as the best possible will continue indefinitely to be the best possible; the day will inevitably come when it can be improved. In the fuller light of the future we may recognize as very unequal periods that we now deem equivalent, and the possibilities of defining pre-Cambrial periods are unlimited. Even now there are announced beneath the lowest fossil-bearing terrane of the Lake Superior region two systems of clastic rocks limited above and below by great unconformities, and Irving demands their recognition as a group, distinct from the Archæan. If his voice heard, the time scale will include an era between the Palæozoal and the Archæal, and this era will supply the needs of the systematist until great additions have been made to our present knowledge of the older rocks.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The resignation of Prof. Prestwich and the continued illness of Prof. Moseley have produced two gaps in the scientific professoriate this term. Though the Professor of Geology has left Oxford, his successor will not be appointed until after Christmas. In Prof. Moseley's absence the work of the morphological department is being carried on by Mr. Hatchett Jackson and Mr. G. C. Bourne, who has just been elected to a Fellowship at New College.

In the department of physics, Prof. Clifton is giving no honour lectures, but has an elementary course on mechanics and acoustics. Mr. Selby is lecturing on elasticity and on electrostatics, both treated mathematically. At Christ Church, Mr. Baynes gives lectures and practical instruction in electricity and magnetism. Sir John Conroy and Rev. F. J. Smith are lecturing on elementary physics at Balliol and Trinity.

The chemical department at the Museum has been strengthened by the addition of Mr. V. H. Veley to the staff; the usual courses of lectures are being given by Mr. Fisher and Dr. Watts, and Prof. Odling is lecturing on glycerine and its derivatives. At Christ Church, Mr. Vernon Harcourt has a class for quantitative analysis, and lectures on elementary chemistry. Sir John Conroy is lecturing on chemical physics at Balliol.

The Physiological Laboratory is continuing its usual work with little alteration. Prof. Burdon Sanderson's lectures are on circulation, respiration, and bodily motion.

Prof. Balfour, besides lecturing on extinct plants for the Professor of Geology, is giving a course on general morphology. Dr. Tylor continues to expound the Pitt-Rivers Collection, a fresh portion which will shortly be rearranged and opened to the public.

Mr. Primrose McConnell is lecturing on the principles of agriculture, mainly for the benefit of India Civil Service candidates.

During this term there will be an examination for Scholarships in Natural Science at Balliol, Exeter, Christ Church, and Trinity jointly, beginning on November 17.

A pamphlet has just been issued from the Clarendon Press giving full information as to the methods of obtaining medical degrees in Oxford, and the instruction in medicine provided by the University.

CAMBRIDGE.—The Museum and Lecture Rooms Syndicate have issued another report pressing for new accommodation for Pathology and Physiology, and suggesting that the department of Pathology, including its Museum, could be located in the old chemistry buildings when the new laboratory is completed. They recommend the building of new rooms for Human Anatomy and Physiology on the Corn Exchange site at the northern end of the Museum site. It is an important feature of this scheme that it would leave free the present Human Anatomy Schools and Museum to be added to the frontage available in Downing Street for a Geological Museum.

Messrs. W. H. Macaulay and W. B. Allcock have been appointed Moderators for the year beginning May 1, 1888. Messrs. J. Larmor and W. Welsh are appointed Examiners in Part I. of the Mathematical Tripos for the same year.

Dr. Smith's prizes for the present year have been adjudged as follows:—(1) Mr. Augustus Edward Hough Love, St. John's College, for an essay on "Small Free Vibrations and Deformation of a thin Elastic Shell," and on "The Force and Forced Vibrations of an Elastic Spherical Shell containing a Given Mass of Liquid." (2) Mr. Arthur Berry, King's College, for an essay on "Joint Reciprocants."

SCIENTIFIC SERIALS.

The Quarterly Journal of Microscopical Science for August 1887, vol. xxviii. part 1, contains the following papers:—On the anatomy of the Madreporia, part 3, by Dr. G. Herbert Fowler, (plates i. and ii.) In this memoir the author deals with the

anatomy of *Turbinaria mesenterina* (?), of *Lophohelia prolifera*, of *Seriatopora subulata*, and of Pocillopora, with a note on the skeleton of Flabellum.—On the anatomy of *Mussa corymbosa*, and *Euphyllia glabrescens*, and on the morphology of the Madreporian skeleton, by G. C. Bourne (plates iii. and iv.)—On the intra-ovarian egg of some osseous fishes, by Dr. Robert Scharff (plate v.)—Observations on the structure and distribution of striped and unstriped muscle in the animal kingdom, and a theory of muscular contraction, by C. F. Marshall (plate vi.) The author concludes that in all muscles which have to perform rapid and frequent movements a certain portion of the muscle is differentiated to perform the function of contraction, and this portion takes on the form of a very regular and highly modified intracellular network. This network, by its regular arrangement, gives rise to certain optical effects, which cause the peculiar appearances of striped muscle; the contraction of the striped muscle-fibre is probably caused by the active contraction of the longitudinal fibrils of the intracellular network; the transverse networks appear to be passively elastic, and by their elastic rebound cause the muscle to rapidly resume its relaxed condition when the longitudinal fibrils have ceased to contract; they are possibly also paths for the nervous impulse.—On the fate of the muscle-plate and the development of the spinal nerves and limb plexuses in birds and mammals, by Dr. A. M. Paterson (plates vii. and viii.)—On the ciliated pit of Ascidians and its relation to the nerve-ganglion and so-called hypophysial gland, and an account of the anatomy of *Cynthia rustica* (?), by Lilian Sheldon, Bathurst Student, Newnham College (plates ix. and x.). Suggests that the original function of the ciliated pit was the aëration of the brain, with which it communicates in the case of Clavellina; where also its posterior part acts as a reservoir to carry off the secretion of the gland.—On the tongue and gustatory organs of *Mephitis mephitica*, by Dr. Frederick Tuckerman (plate xi.) This memoir is preceded by an interesting account of the literature relating to the position and structure of the taste organs of vertebrates.—On the quadrate in the Mammalia, by Dr. G. Baur. He thinks that there is little doubt but that the quadrate of the lower vertebrates is contained in the sygomatic process of the mammals.—On the hæmoglobin crystals of rodents' blood, and on an easy method of obtaining methæmoglobin crystals for microscopic examination, by Dr. W. D. Halliburton.

Bulletin de l'Académie Royale de Belgique, August.—Note on the oscillations of a pendulum produced by the displacement of the axis of suspension, by E. Ronkar. The object of these researches is to ascertain the possibility of recording the slight oscillations in the crust of the earth by means of a freely suspended pendulum. It is shown that the pendulum retains a movement imparted by a certain number of horizontal undulating impulses, whenever the duration of the oscillation of the pendulum is the same as that of the axis, but not otherwise. From this may be deduced an experimental process for determining the periodical irregularities in the movement of diurnal rotation.—On the colloidal sulphuret of cadmium, by Eug. Prost. To the colloidal solutions of arsenious, stannic, and other sulphurets already determined, the author here adds the sulphuret of cadmium, which was hitherto known only in the insoluble state. He obtains a colloidal solution of this compound by passing hydrosulphuric acid through water holding in suspension freshly precipitated cadmic sulphur, and afterwards eliminating by the action of heat the hydrosulphuric acid dissolved in the liquid. A spectroscopic study of this clear yellowish liquid shows that the cadmic sulphur is really in a state of solution, the solution presenting all the characters hitherto ascribed to all dissolved colloidal substances.—Description of some new Cucurbitaceæ, by M. Alfred Cogniaux. This paper contains an account of fourteen new species and of several varieties, forming an important addition to the author's general monograph of this family published in De Candolle's "Monographiæ Phanerogamum."

SOCIETIES AND ACADEMIES.

London.

Entomological Society, October 5.—Dr. Sharp, President, in the chair.—Mr. Jacoby exhibited a specimen of *Aphthonoides beccarii*, Jac., a species of Haltica having a long spine attached to the posterior femora; also a specimen of *Rhagiosoma madagascariensis*.—Mr. Stevens exhibited a very dark specimen of *Crambus perlellus* from the Hebrides, which its captor supposed to be a new species. Mr. Porritt remarked that this brown form of *Crambus perlellus* occurred at Hartlepool with the ordinary typical form of the species, and was there regarded as only a variety of it.—Mr. Slater exhibited a specimen of *Gonepteryx cleopatra*, which was stated to have been taken in the North of Scotland. Mr. Jenner Weir remarked that although the genus *Rhamnus*—to which the food-plant of the species belonged—was not a native of Scotland, some species had been introduced, and were cultivated in gardens.—Mr. South exhibited about 150 specimens of *Boarmia repandata*, bred from larvæ collected on bilberry in the neighbourhood of Lynmouth, North Devon, including strongly marked examples of the typical form, extreme forms of the var. *conversaria*, Hüb., a form intermediate between the type and the variety last named, and examples of the var. *destrigaria*, Haw. Mr. South said that an examination of the entire series would show that the extreme forms were connected with the type by intermediate forms and their aberrations.—Mr. Poulton exhibited young larvæ of *Apatura iris*, from the New Forest; also eight young larvæ of *Sphinx convolvuli* reared from ova laid on the 29th of August last. He said the life-history of the species was of extreme interest, throwing much light upon that of *Sphinx ligustri*, as well as upon difficult points in the ontogeny of the species of the allied genera *Acherontia* and *Smerinthus*. Mr. Stainton said he was not aware that the larvæ of *Sphinx convolvuli* had ever before been seen in this country in their early stages. Mr. McLachlan remarked that females of this species captured on former occasions, when the insect had been unusually abundant, had been found upon dissection to have the ovaries aborted.—Mr. R. W. Lloyd exhibited specimens of *Elater pomonæ*, and of *Mesosa nubila*, recently taken in the New Forest.—Mr. Porritt exhibited a series of melanic varieties of *Diurnea fagella*, from Huddersfield, and stated that the typical pale form of the species had almost disappeared from that neighbourhood.—Mr. Goss exhibited, for Mr. J. Brown, a number of puparia of *Cecidomyia destructor* (Hessian Fly), received by the latter from various places in Cambridgeshire, Norfolk, Suffolk, and Wiltshire. He also exhibited a living larva of *Cephus pygmæus*, Lat. (the Corn Sawfly), which had been sent to Mr. Brown from Swaffham Prior, Cambridgeshire, where, as well as in Burwell Fen, the species was stated to have been doing considerable damage to wheat crops. Mr. Verrall, in reply to a question by Mr. Enock, said he believed that the Hessian Fly was not a recent introduction in Great Britain, but had been here probably for hundreds of years. He admitted that he was unable to refer to any but recent records of its capture. Prof. Riley said he was unable to agree with Mr. Verrall, and believed that the Hessian Fly had been recently introduced into this country. Its presence here had not been recorded by Sir Joseph Banks, by Curtis, by Prof. Westwood, by the late Mr. Kirby, or by any other entomologist in this country who had given especial attention to economic entomology. It seemed highly improbable, if this insect had been here so many years, that its presence should have so long remained undetected both by entomologists and agriculturists. Prof. Riley said it had been stated that the insect was introduced into America by the Hessian troops in 1777, but this was impossible, as its existence at that date was unknown in Hesse. Mr. McLachlan, Capt. Elwes, Mr. Verrall, Mr. Jacoby, and Dr. Sharp continued the discussion.—Mr. J. Edwards communicated the second and concluding part of his "Synopsis of British *Homoptera-Cicadina*."—Prof. Westwood contributed "Notes on the life-history of various species of the Neuropterous genus *Ascalaphus*."—Capt. Elwes read a paper "On the Butterflies of the Pyrenees," and exhibited a large number of species which he had recently collected there. Mr. McLachlan said he spent some weeks in the Pyrenees in 1886, and was able to confirm Capt. Elwes' statements as to the abundance of butterflies in that part of the world. The discussion was continued by Mr. Distant, Mr. White, Dr. Sharp, and others.

Mineralogical Society, October 25.—Anniversary Meeting.—Mr. L. Fletcher, President, in the chair.—After the reading of the Report, the following were elected Officers and Council for the ensuing session:—President: L. Fletcher. Vice-Presidents: Rev. S. Haughton, F.R.S., W. H. Hudleston, F.R.S. Council (in place of Messrs. Burghardt, Danby, Dobbie, and Lewis, the retiring Members): Prof. A. H. Church, Townshend

M. Hall, Colonel C. A. M'Mahon, J. Stuart Thomson. Treasurer: Rev. Prof. T. G. Bonney, F.R.S. General Secretary: R. H. Scott, F.R.S. Foreign Secretary: T. Davies. Auditors: B. Kitto, F. W. Rudler.—The following papers were read:—On a meteoric iron, containing crystallized chromite, found in Greenbrier Co., West Virginia, about the year 1880, by L. Fletcher, President.—On the nature and origin of clays, by J. H. Collins.—Note on the occurrence of what may prove to be a new mineral resin, by J. Stuart Thomson.—On a variety of glaucophane from the Val Chivone (Cottian Alps), by Rev. Prof. T. G. Bonney, F.R.S.—On the discovery of leucite in Australia, by Prof. J. W. Judd, F.R.S.—On proustite containing antimony, by H. A. Miers and G. T. Prior.—Description of a new student's goniometer, by H. A. Miers.—On rutile needles in clays, by J. J. H. Teall.

PARIS.

Academy of Sciences, October 24.—M. Janssen in the chair.—On naphthol as an antiseptic, by M. Ch. Bouchard. From the experiments here described it is shown that naphthol, hitherto limited to the local treatment of certain cutaneous diseases, may with perfect safety be applied inwardly. Its antiseptic and toxic properties have been accurately determined, with the result that, owing to its slight solubility, it is to be preferred in certain cases to all known antiseptic medicines.—Remarks on the physical principle on which is based M. Clausius's new theory of steam-motors, by M. G. A. Hirn. The view here contested is that the cylinder may be regarded as impermeable to heat, and consequently that the exchange of heat between its walls and the steam at each stroke of the piston is a factor which may be neglected by the practical mechanician. M. Hirn claims that most English and American engineers have adopted his views in the "Hirn-Zeunner controversy."—On the congelation of ciders, by M. G. Lechartier. The author's experiments make it evident that the fermentation of ciders is not destroyed but only diminished even after being kept for nine days at a temperature of 18° C. below freezing-point.—Remarks accompanying the presentation of the "Statistique de la Superficie et de la Population des Contrées de la Terre," by M. E. Levasseur. This work, which appeared originally in the *Bulletin de l'Institut international de Statistique* for 1886–87, comprises 103 tables, in three parts—the first devoted to Europe, the second to the other divisions of the globe, the third to general conclusions and comparative details for the whole earth. In this part the area and population of the various divisions of the world are thus tabulated for the year 1886:—

	Area in millions of square kilometres.	Population. In millions.	Density per square kilometre.	Ratio to the whole population of the world.
Europe	10·0	347	34	23·4
Africa	31·4	197	6	13·3
Asia	42·0	789	19	53·2
Oceania	11	38	3·5	2·6
North America	23·4	80	3·4	5·4
South America	18·3	32	1·7	2·1
	136·1	1483	10·9	100·0

It is pointed out in the introduction that nearly two-thirds of mankind are concentrated in a relatively small space, about 11 millions of square kilometres, or one-twelfth of all the dry land, divided into three great groups: West, Central, and South Europe (245 millions of inhabitants, and 3·5 millions of kilometres); the Anglo-Indian Empire (254 and 3·6); and China, with Manchuria and Japan (430 and 4).—On the third scientific voyage of the *Hirondelle*, by Prince Albert of Monaco. Besides many hundreds of floats sent adrift between the Azores and Newfoundland, several captures were made from great depths with the sounding-gear, which worked easily down to 3000 metres from the surface. Amongst the prizes were several undescribed fishes, Gorgons, siliceous Sponges of the Hexactinellid family, a soft Urchin (*Phormosoma*), numerous Amphipod and Isopod Crustaceans, Solasters, Ophiures, and Hyas of great size, besides a moon-fish weighing nearly 300 kilogrammes, and furnished with a true caudal appendage.—On Newton's chromatic circle, by M. G. Govi. It is shown that this law, of which Newton himself offered no demonstration, is often at fault, because it expresses no certain theoretic principle, nor any rigorously observed theoretic fact. Nevertheless it may still yield approximately correct useful results when it is required to express the complex sensations experienced by the organ of sight.—Positions of Brooks's Comet (January 22, 1887) measured with the 8-inch equatorial of the Observatory of Besançon, by M. Gruey. The positions are calculated for the period ranging from February 24 to April 29.—On magnetizing by influence, by M. P. Duhem. The author communicates the chief results of some studies based on the principles of thermodynamics, and undertaken for the purpose of removing some of the difficulties presented by Poisson's theory.—Action of sulphureted hydrogen on the salts of cobalt, by M. H. Baubigny. Some years ago the author showed that all the salts of nickel are transformed to sulphides when their solutions are treated with hydrosulphuric acid at the ordinary temperature. He now shows that a like treatment of the salts of cobalt yields very similar results.—On the quantitative analysis of titanic acid, by M. Lucien Lévy. A new method of analysis is described, which is more rapid and yields more accurate results than that hitherto in use.—On certain processes capable of increasing the resistance of the organism to the action of microbes, by M. Charrin. It is shown, by experiments carried out on rabbits, that under specified conditions the resisting power of the animal may be greatly increased and rendered more or less complete and lasting by inoculating or injecting the soluble products of the cultivated virus of certain microbes.

CONTENTS.

THURSDAY, NOVEMBER 10, 1887.

A CONSPIRACY OF SILENCE.

THE Duke of Argyll is eminent as a statesman, and has won distinction as a man of science. The mental qualities, however, which lead to success in these capacities are widely different; nay, in the opinion of some, are almost oppugnant. To the man of science, truth is as a "pearl of great price," to buy which he is ready to part with everything previously obtained; to the statesman, success is the one thing needful, for the sake of which hardly any sacrifice appears too great. This is not said wholly as a reproach: it "takes all sorts to make a world." The ardour of the follower of the ideal, which may degenerate into recklessness, is wholesomely checked and beneficially qualified by the calmness of one who has to deal practically with mankind, and has learned by experience that evolution rather than catastrophic change is the law of life, and is in accordance with the analogy of Nature. Still the two types of mind are commonly diverse, and the Duke of Argyll has recently afforded a remarkable instance of the extreme difficulty of combining in one person these apparently opposite characters.

This instance is afforded by an article which appeared in the *Nineteenth Century* for September last, and is commented on by Prof. Huxley in the number for the present month. The Duke's article bears the somewhat imposing title of "The Great Lesson." Prof. Huxley's reply forms a part of an article entitled "Science and the Bishops." As the charge which the Duke has in effect brought against men of science is a very grave one, and as some of the readers of NATURE may not be constant readers of the chief monthly magazines, a brief notice of both accusation and reply may not be without interest.

The moral of "The Great Lesson" is, practically, "beware of idolatry." The scientific world, in the Duke's opinion, has been for some time bowing down to the idol of Darwin and the theory of evolution, which is the fundamental dogma of that cult. Like a prophet of old he raises a warning voice, and points out that the feet of the golden image are in part composed of clay. In the North has been hewn the stone which shall shatter those fragile supports and lay the idol prone in the dust! To abandon metaphor, this is the state of the case. Among the results of Mr. Darwin's labours during the voyage of the *Beagle* in the years 1831-36, when he accumulated that vast store of observations which served as a foundation for "the Origin of Species by means of Natural Selection," was a theory of the formation of Coral Reefs and Atolls, set forth in a volume entitled "On the Structure and Distribution of Coral Reefs" (published in 1842 and republished in 1874). Of this theory the Duke gives an outline in "The Great Lesson," executing this portion of his task so fully in the spirit of a just judge, and with so little of the craft of an advocate, as to leave nothing to be desired for lucidity of statement and cogency of reasoning. In fact, in the judge's summing up, the case for the defence appears stronger than that for the prosecution—so much so, indeed, as to suggest that the difference is due to their inherent merits rather than to the mode of statement. However, be that as it may, the Duke thus pronounces judgment, and in so doing passes a censure, stinging if deserved, on the men of science of this generation.

These are his words (*Nineteenth Century*, p. 305):—

"Mr. Murray's new explanation of the structure and origin of coral reefs and islands was communicated to the Royal Society of Edinburgh in 1880, and supported with such a weight of fact and such a close texture of reasoning that no serious reply has ever been attempted. At the same time, the reluctance to admit such an error in the great idol of the scientific world, the necessity of suddenly disbelieving all that had been believed and repeated in every form for upwards of forty years, of cancelling what had been taught to the young of more than a whole generation, has led to a slow and sulky acquiescence, rather than to that joy which every true votary of science ought to feel in the discovery of a new truth, and—not less—in the exposure of a long-accepted error."

Again:—

"The overthrow of Darwin's speculation is only beginning to be known. It has been whispered for some time. The cherished dogma has been dropping very slowly out of sight. Can it be possible that Darwin was wrong? Must we indeed give up all that we have been accepting and teaching for more than a generation? Reluctantly, almost sulkily, and with a grudging silence so far as public discussion is concerned, the ugly possibility has been contemplated as too disagreeable to be much talked about; the evidence old and new has been weighed again and again, and the obviously inclining balance has been looked at askance many times. But, despite all averted looks, I apprehend it has settled to its place for ever, and Darwin's theory of the coral islands must be relegated to the category of the many hypotheses which have indeed helped science for a time, by promoting and provoking further research, but which in themselves have now finally kicked the beam."

This, then, is "The Great Lesson":—

"It is that Darwin's theory is a dream. It is not only unsound, but is in many respects the reverse of the truth. With all his conscientiousness, with all his caution, with all his powers of observation, Darwin in these matters fell into errors as profound as the abysses of the Pacific."

This is plain speaking. In words which admit of no ambiguity the Duke declares that Darwin was wrong; that Mr. Murray set him right; and that the latter, instead of receiving a welcome, was met with a virtual conspiracy of silence on the part of scientific men. Of these three assertions—which are to a considerable extent independent one of another—the first and second are obviously very much matters of opinion, because, if the third statement be true, it is clear that no verdict has been delivered by experts, but that, like an Irish jury, they have professed themselves unable to agree, because the facts were so strong that even they could not bring in a verdict of acquittal. The third assertion, however, is much more a matter of fact, not difficult to substantiate, and at any rate, if incorrect, easy to disprove.

In regard, then, to the first and second it may suffice to follow Prof. Huxley's example and be content with expressing a doubt as to the accuracy of the Duke's

assertions. In the face of statements so definite as those quoted above, this may seem presumptuous. They read almost like the sentence of an ecclesiastical court, which it is heresy to question. *Caledonia locuta est, causa finita est*, seems to be their tone; and if one whisper a doubt, one expects the familiar conclusion, *Anathema sit!* But men of science, as all the world knows, are sceptics. Have they yet awakened and rubbed their eyes, and said of Darwin's theory "Lo! it was a dream"? What says Prof. Huxley? He asserts that Darwin's confidence in the accuracy of his own theory was not seriously shaken, as the Duke alleges, and quotes as conclusive evidence a letter from Prof. Judd, who gives the results of a conversation which he had with Darwin no long time before the death of the latter. Prof. Huxley also intimates that to himself—though tolerably familiar with coral reefs—the new theory is at first sight so far from fascinating that, until he can devote a considerable time to a re-examination of the whole subject, he must be content to remain "in a condition of suspended judgment," and that Prof. Dana, "an authority of the first rank on such subjects," has pronounced against the new hypothesis in explicit terms. Undoubtedly, Mr. Murray has obtained distinguished converts, but with such differences of opinion among those best qualified to judge, it is certainly going further than is warranted by facts to insinuate if not to assert that he has convinced the scientific public. Very probably more than a minority of them are in my own position, which perhaps I may be pardoned for stating. They, like myself, have never had the opportunity of forming an independent judgment upon the matter, but they see some very serious difficulties—difficulties which are of a general rather than of a special nature—in the new explanation. At present these difficulties do not appear to them to have been overcome; so that, while admitting that Mr. Murray's hypothesis may sometimes apply, and that Darwin either may have expressed himself a little too sweepingly, or may have been understood so to do, the theory of the latter is capable of a more general application, and presents less serious general difficulties, than does that of Mr. Murray.

We come, then, to the third charge, which is the most serious one, because it affects the morality of scientific men; and many of them, like myself, are old-fashioned enough to resent being called a knave more than being called a fool. Has Mr. Murray been met by "a conspiracy of silence"? The Duke, in asserting this, must have been strangely oblivious of, or, among the cares of a statesman, have failed to keep himself *au courant* with, the literature of geology. Prof. Huxley denies the assertion, and adduces in his support an answer to an inquiry which he had addressed to Prof. Judd. The facts, according to these authorities, are briefly as follows:—Mr. Murray's views were duly published, as the Duke himself states; they were favourably regarded by the authorities at the *Challenger* Office; they were expounded, one might almost say advocated, on more than one occasion (*e.g.* in this very journal) by Dr. A. Geikie. His text-book in the year 1882 not only took the leading place, as it still does, but also was then the only complete text-book on a large scale for this country. On p. 468 is a full statement of Mr. Murray's views. They have also been referred to at more or less length in many treatises and journals, both English and foreign. As Prof. Judd remarks, "If this be a 'conspiracy of silence,' where, alas! can the geological speculator seek for fame?"

Thus the main charge is disproved. One special item in it, however, as peculiarly offensive, yet calls for a brief notice. The Duke states: "Mr. John Murray was strongly advised against the publication of his views in derogation of Darwin's long-accepted theory of the coral islands, and was actually induced to delay for two years." Now, if these words do not amount to an imputation of bad faith on the part of Mr. Murray's adviser, and are not by insinuation extended to others, I do not know what they mean, or why they have been penned. But, as Prof. Huxley observes, "whether such advice were wise or foolish, just or immoral, depends entirely on the motive of the person who gave it." The remark is perfectly just. Who, I would ask, who is old enough to look back on a quarter of a century of work, has not occasionally said, "Wait a bit," to some younger friend, who has come in the first incandescence of a brilliant hypothesis? I have so sinned. Sometimes I have been wrong and my young friend right, but not always. Still, I know myself fallible. As the late Master of Trinity said, "We are all fallible mortals, even the youngest amongst us." Yet I am not ashamed. I will not put on sackcloth and ashes, and I mean to sin again. Perhaps it is because I am naturally unimaginative; perhaps I am come to the season of autumn leaves; but I have always looked askance at a brilliant hypothesis, and now distrust it more than ever. I have lived long enough to see many a one go up *whoosh!* like a sky-rocket, all stars and sparks, and come down exploded, all stick and stink!

So the "great lesson" has been read, and the scientific world, I fear, has not repented or rent its clothes. But it has heard, and not without indignation. The Duke of Argyll has made grave charges against the honour and good faith of men of science, and they ought to be grateful to Prof. Huxley for his prompt repulse of the attack and his stern rebuke of the assailant. As it seems to me, reply is only possible on one point—namely, the special charge mentioned above. Hence the Duke of Argyll is bound to establish or to withdraw the accusation.

Men of science are justly sensitive on this question. Doubtless they are no more exempt from human frailty than any other class of men: we all fail sometimes—nay, too often—to live up to our ideal standard; still, such shortcomings are not common, and anything like a "conspiracy of silence" or any kind of scientific "boycotting" is a thing so improbable as to be almost incredible. Each man must testify according to his own experience; so in conclusion, though it may be deemed impertinent, I will express my own. I have lived now for not a few years among the rank and file of scientific men on more intimate terms than can have been possible for the Duke of Argyll, owing to his exalted station and his high occupations of State, and I am bound to declare that, in a fairly wide experience, I have never found men as a class less self-seeking or more earnest in their desire for truth, more steadfast as friends, or more generous as antagonists.

T. G. BONNEY.

A TEXT-BOOK OF ALGEBRA.

A Text-book of Algebra. By W. Steadman Aldis, M.A (Oxford: Clarendon Press, 1887.)

THIS work is, as we are told in the preface, "the outcome of lectures delivered in the College of Physical Science at Newcastle-upon-Tyne." It discusses, more fully than is usual in books on algebra, the fundamental principles of the science, and its aim is to be of service to the independent student who has not the advantage of "access to large libraries, or intercourse with other mathematical scholars." The object of the author, as might be expected from his eminence as a mathematician and his experience as a teacher, is, in our judgment, likely to be successfully attained in the use of his work. The book is hardly adapted for those students whose object it is to attain such skill and facility in algebraical work as is necessary to face an examination paper in algebra, set by the University examiner of the present day. The examples, though sufficient for illustrating the principles, are not numerous enough for the purpose of developing such skill, nor selected with that special object; and such aids to the attainment of exactness as the various tentative methods of finding the factors of algebraical expressions of different forms, and other aids to insight into their constitution, are only incidentally alluded to. Still, even this class of students will find it a book worthy of reference, when they are revising the fundamental principles on which the science is based, and realizing that all its operations are reducible to a few fundamental laws.

The book is divided into four sections, treating respectively of the fundamental laws and the algebraical operations founded thereon, of equations, of series, and of arithmetical applications.

In the first chapter, headed "Arithmetical Notions," the arithmetical basis of algebra is laid down in a careful discussion of the laws of the simple operations of arithmetic; the commutative laws of addition and multiplication, and the distributive and associative laws of multiplication, being shown to result, both for integral and fractional numbers, from our fundamental conceptions of number. In this chapter particular numbers only are used, and the expression of the results by the use of letters denoting any numbers whatever is relegated to the following chapter on "Algebraical Notation." This would seem to indicate that Prof. Aldis agrees with a commonly accepted notion, that algebra begins with the introduction of letters to denote unspecified numbers. We hold, on the contrary, that, in arithmetic, letters may, and ought to, be freely used to express the unknown quantities of a question, or to sum up in general terms properties of numbers or rules which have been established for solving particular problems; and that only when a result has been obtained by means of organized algebraical operations, instead of by ordinary reasoning, has algebra, properly so called, been employed.

In the second chapter the general results of the first are summed up in a series of formulæ, numbered (1) to (21), to which are afterwards added others, numbered (22) to (25), expressing the laws of indices. The extension of the use of the signs + and − to indicate opposite affections of the quantities denoted by the letters to which they are prefixed is carefully explained; and it is shown by the illustration of "steps" that still wider interpretations may be given to the symbols and formulæ. Upon this foundation the subsequent chapters dealing with the elementary operations on algebraical expressions are based, explicit reference being made to one or other of the formulæ by its number to justify each step in the establishment of the various processes. This method of procedure is sound and logical in itself, yet we fear that the effect of referring to so many apparently independent formulæ must be confusing to the student, and likely to give him incorrect ideas as to the number of independent laws to which all algebraical operations are reducible. This might have been avoided by a preliminary discussion of the formulæ, showing that with the understanding that the letters may denote either positive or negative quantities they are reducible to some five or six fundamental laws, to which, rather than to the particular exemplifications of the laws in these formulæ, it would have been better in the sequel to refer. Thus the formulæ numbered (1), (2), (3) are all included in the commutative law of addition or aggregation—that in an aggregate of positive and negative terms the order of aggregation is indifferent: so, too, (3), (4), (5), (6) are summed up in the "Rule of Signs"—that the addition of a positive aggregate of terms is equivalent to the addition of each term with its actual sign, and that of a negative aggregate is equivalent to the addition of each term with its sign reversed, and similarly for other groups of the formulæ.

The discussion of the highest common factor, lowest common multiple, and fractions, is followed by a chapter on fractional and negative indices, at the outset of which the question of incommensurables is discussed, and it is shown by apt illustrations that the literal symbols of algebra may represent incommensurable as well as commensurable quantities, since the same laws hold good for the former as have been established for the latter. We should have expected that, as a natural sequel to this chapter, logarithms and their properties and uses would have been discussed, but we find no mention even of the word till we come, much later on in the book, to the Exponential Series. There is no logical necessity for postponing the discussion of the nature and properties of logarithms till we can show how their values can be practically calculated, while the enormous practical importance of an acquaintance with their theory and use is a good reason for its introduction at the earliest possible stage.

A chapter on surds and impossible quantities concludes the first section. In this it is shown that the impossible quantity of ordinary algebra is only relatively impossible, since it becomes interpretable as an "operational quantity" when the letter to which it is attached is taken to denote a length in a definite direction—a view which is further illustrated by the discussion of the cube roots of unity as "operational quantities." This, though not a full account of the matter, is satisfactory so far as it extends, and sufficient for the student at this stage.

The specially distinctive features of Prof. Aldis's work are contained in this first section. We trust we have made it plain that we think it well worthy of the study of

the student who desires to attain a clear, logical view of the foundations of algebraical science. The remaining sections demand less comment as presenting less novelty of treatment.

The most noticeable feature in the section on equations is the introduction of the notation, and a discussion of some of the properties, of determinants. We cannot but regret the space that is devoted in this section to the discussion of the processes for the extraction of square and cube roots in the old traditional shape. In the chapter on division the law of formation of the quotient and remainder of a rational integral function of x after division by $x-a$ has been established. Starting from this, a discussion involving nothing more than elementary considerations would lead up to Horner's process in all its generality, which might then be exemplified in the extraction, not only of square and cube roots, but of roots of any degree, both for algebraical expressions and for numbers. How long shall we have to wait for a due recognition in elementary treatises of this comprehensive method, which, whether from a theoretical or from a practical point of view, is one of the most valuable results of a study of algebra?

The section on series commences with the establishment of the usual formulæ for permutations and combinations, as preliminary to the binomial theorem. We observe with satisfaction that the path to the proof of each general formula is smoothed by the prior discussion of a particular case, by which, as every good teacher knows, the principle involved may be more distinctly brought out than in the general proof, where it is too likely to be lost sight of in the generality of the symbols employed. To the chapter on geometrical progression is attached, as we think it always should be, one of its most important applications—namely, that to compound interest and annuities. The chapters on the binomial theorem and other series usually discussed in elementary algebra are clear and satisfactory, though we think a little more prominence should have been given to the distinction of *convergent* and *divergent* series, and a fuller discussion of the tests of convergency and divergency.

The last section includes under the general heading of "Arithmetical Applications," chapters on proportion, continued fractions, indeterminate equations (limited to those of the first degree), inequalities, notation and numbers, and probabilities. It is not intended, we presume, that the study of some at least of these should be postponed till after the study of the previous sections, but that as *Applications* they do not form a necessary part of the general sequence of algebraical results, though it appears to us rather strange that a place for proportion, at any rate, should not have been found in such sequence.

R. B. H.

PRACTICAL BOTANY.

Practical Botany. By F. O. Bower and Sydney H. Vines. Part II. (London: Macmillan and Co., 1887.)

ABOUT twelve or fourteen years ago there occurred in England two events which have had so marked an influence on the development of scientific botany in this country that they are likely never to be lost sight of by our younger school of morphologists and physiologists. One of these events was the introduction into this country of the teaching of Prof. Sachs, of Würzburg; the second and even more important one was the institution by Mr. Thiselton Dyer of a course of botanical instruction at South Kensington on a scale never before attempted. Those who had the good fortune to attend Mr. Dyer's courses of practical botany in the well-known laboratory at what is now the Normal School of Science must always carry with them the stimulating remembrance of the thorough teaching there instituted; and the effect of the exact instruction and inspiriting demonstration so efficient at South Kensington can be obviously traced in the excellent teaching and work of the enthusiastic younger botanists of to-day. The influence took effect on the early development of the present productive botanical laboratories at Cambridge and elsewhere, and the stimulus has since radiated thence in all directions, as is shown not only by the numerous publications of the last eight or ten years, but also by contributions to the new journal, *The Annals of Botany*, just published by the Oxford Clarendon Press, and by the activity and discussions of the botanists at the recent brilliant meeting of the British Association in Manchester.

The salient features of the new course of structural botany were the thorough study of leading types of the vegetable kingdom by means of material dissected and prepared by the students themselves, and the stress laid on the rule that the students should carefully draw what they saw, and thus gather their ideas at first hand. The method was similar to that employed by Prof. Huxley in his course on animal morphology.

It is evident that the little hand-book of practical botany now under review is the outcome of experience gained in continuing this important method of instruction. Part I. of the present work was published two years ago, and dealt with selected types of the Vascular plants. Part II. is now before us, and completes the scheme. It comprises studies of the chief types of lower Cryptogams, from the moss downwards.

We have already pointed out that the essential features of the new teaching are the exact and thorough study of types. Nothing is assumed; but the students are urged to see everything for themselves, and to draw all they see. These important points decide the plan of the work under review. It will be found an excellent and trustworthy guide to any who use it with the types at hand: it will be all but useless to the mere crammer, for there are no illustrations to take the place of actual objects in producing impressions on the student's mind; no lengthy descriptions to interfere with the directness or clearness of the impressions; and no classified "tips" to vitiate and confuse the teaching. We regard it as an excellent sign of the progress of botany in this country that an English work of this description should be forthcoming, and students are greatly indebted to Dr. Vines and Dr. Bower, and those who have contributed to this admirable little monument of practical teaching.

As special features in the book we may commend the selection of types; they are good, for the most part easily obtained, and well known. The treatment of the types in the book is clear, concise, and yet sufficient. The usage of bolder lettering for the chief word in the para-

graph is an admirable device for fixing the student's attention on one thing at a time, and is aided by the numbering and lettering of the paragraphs. The division into sections dealing with groups of characters, leading the student on from the more obvious features to those less easily investigated, also stamps the work as that of experienced teachers, and is eminently English.

The only part of the plan to which objection is likely to be raised by teachers is what may perhaps be termed the reversal of the order of the types. We are ourselves inclined to the opinion that it would have been better to begin with the more lowly organized types, and work upwards to those in which the anatomy and histology become more complex. There is much to be said in favour of the method adopted, but we think that the following two objections to it alone outweigh all we have heard in its favour.

(1) The types are obviously selected as illustrating the chief structural peculiarities of plants, and it might be better to at least indicate the relations of these structures in an order more in accordance with their probable development in the vegetable kingdom.

(2) The plan of teaching which marks the book is the educational one, *i.e.* the observer is led on from simple to less simple ideas. This is only carried out consistently, however, within the individual sections of the book: why should it not be followed throughout the work?

Of course the objection may be anticipated that the sections really lead the student on from the macroscopic to the microscopic characters, and that Algæ and Fungi, for instance, are less easy to investigate, and therefore come last, because they involve the use of the higher powers of the microscope so much. We do not admit that this latter is a difficulty, however, and in reply would simply propose for psychological study the mental attitude of a tyro struggling with his first transverse section of a sunflower-stem. The cutting, preparation, mounting, and finally the involved pattern of cell-walls which he has to unravel, at once plunge him into difficulties at least as great as those met with on the threshold of the study of the Algæ. Moreover, there is evidence in the work that the student is supposed to be acquainted with the use of the microscope, such as would be obtained from a proper course of elementary biology.

Of course, however, it is always open to a teacher to reverse the order of the types in the book; and it only remains for us to say a few words regarding some of those employed in the second volume. *Polytrichum* is selected as the chief type of the mosses, and we think Dr. Bower has done well to illustrate the details of structure by this complex form, surmounting the difficulty presented by its peculiar sporogonium by a comparative study of that of *Funaria*—itself an excellent type. We are glad to see *Marchantia* treated in detail. It is, of course, an out-of-the-way form, and is peculiar even in its own group, but it is an instructive plant, and one that has earned a reputation from the physiological lessons it teaches us. *Polysiphonia* serves as the chief type of the red sea-weeds, and although it has many peculiarities, it has the advantage of being common: the structures of several other Florideæ are shortly compared with that of *Polysiphonia*. *Fucus serratus* forms an excellent type for the study of the brown sea-weeds, and as it is easily obtained, it should be employed in every laboratory course: the details of the actual process of fertilization still offer an interesting problem to any intelligent student, but the chief stages in the process are not difficult to observe.

Passing to the green Algæ, *Œdogonium* seems to us a type well worth thorough study in the laboratory; it is by no means uncommon, and an effort should be made to introduce a definite species of the larger forms as a type. Short studies of *Coleochæte* and of *Ulothrix* are also given. *Vaucheria sessilis* is offered as an example of the Siphoneæ, and we are glad to see it brought well into the foreground; this again is a plant of increasing importance as an instructive plant. Most of the details of the process of fertilization in this Alga offer less difficulties than is commonly supposed, and students should be encouraged to spend some time on their study. A short *résumé* of the main points is given. No doubt the presence of *Protococcus* or *Hæmatococcus* in schedules of elementary biology explains its omission from the present work: *Pleurococcus* and *Volvox* are given, however, and they illustrate several points of importance. In spite of—or perhaps on account of—its very marked peculiarities, we look upon *Spirogyra* as one of the most instructive types that the student can examine, and Dr. Bower has done well to give it a prominent position. It deserves more attention, however, and we would strongly urge an exhaustive treatment of its life-history, germination, and some of the physiological lessons it teaches.

Passing over less important forms, we may now say a few words respecting the Fungi given as types for study. The first section is devoted to *Agaricus*, and a capital study of the structure and histology of the common mushroom is given. Then follows an equally good account of the Æcidiomycetes. Of Ascomycetes, we have *Peziza*, *Parmelia*, *Claviceps*, and *Eurotium*, as types of the chief great groups. A word as to *Peziza*. It is an excellent type, and certain forms can be cultivated, and we hope that in a second edition the author will see his way to introducing a fuller account of some one species. At the same time we are not sure that *Ascobolus* is not a better form for the present purpose: it can be easily cultivated, and its small size is an advantage, since perfect sections can be obtained across the whole plant. Another excellent type is also introduced in the study of the Peronosporeæ. English students are only now becoming aware of the theoretical importance of this group, and we are very glad to see Dr. Bower's section on *Pythium de Baryanum*: it cannot be too well understood that *Pythium* is one of the few parasitic Fungi which may be easily cultivated and followed through all its phases of development in the laboratory. For our own part, we regard it as the best of all Fungi for study, and its life-history and simple structure ought to be thoroughly investigated in every botanical course. It has the additional advantage of being also a saprophyte, and can be cultivated on dead organisms. The Mucorineæ are exemplified by *Mucor* and *Sporodinia*. No type of the Ustilagineæ is given.

Enough has been said to show that the volume pretends to no more than it can fairly claim, and we regard it with confidence as a praiseworthy and successful attempt to record for the benefit of a wide class of

students the methods of teaching so well introduced and so thoroughly carried out in the laboratory at South Kensington, the birth-place of the modern English school of morphological botany. It now remains for one of our competent younger botanists to prepare a course of practical instruction in the physiology of plants, introducing the experiments employed in our best laboratories; and there are signs that such a volume will meet with a hearty welcome from students of botany in this country. The importance of the subject needs no comment.

OUR BOOK SHELF.

A Chapter in the History of Meteorites. By the late Walter Flight, D.Sc., F.R.S. (London: Dulau and Co., 1887.)

THIS work, though left incomplete by the early death of its author, will be found of great service by all who are interested in meteoric studies. The first 144 pages were printed off twelve years ago, and were thus safely beyond revision. The rest of the work has been revised, and the whole has been prepared for press, by editors who, perhaps wisely, have chosen to be anonymous: their part of the task we may dismiss with the remark that it appears to have been executed with at least ordinary care. The task of the author has been to give a brief summary of the memoirs which have been published relative to meteorites since the year 1868, and thus to furnish an appendix to the work of Buchner. To collectors of meteorites such a convenient summary of memoirs, themselves scattered over a wide range of periodicals, chiefly foreign, is invaluable. There are seven plates and six woodcuts: the frontispiece is an excellent engraving of Chladni, who did so much to compel men of science to recognize the reality of meteoric falls. There is also a hand-painted picture of the wonderful meteorite of Busti, in which two minerals new to terrestrial mineralogy were discovered by Maskelyne. In an introduction there is a short sketch of the life and work of the author. Only 240 copies have been printed; the proceeds of their sale are to be added to the Flight Memorial Fund, which at present amounts to £317.

A Hand-book for Steam Users. By M. Powis Bale, M.I.M.E., A.M.I.C.E. (London: Longmans, 1887.)

MR. BALE'S little hand-book supplies a want long felt by steam users. Its contents are entirely of a practical nature, and the technical terms used are very properly those of the ordinary mechanic. The book embraces the whole of the many duties of the engine-driver and fireman, and explains to them what to do, and what not to do, under varying circumstances. The arrangement of the information is simple and effective, the writer evidently knowing how to get at the understanding of those for whom the book is written.

The information and rules given are eminently practical, and will prove very useful to those steam users who do not pretend to be engineers. In the preface we are told that the author has for many years urged the necessity of a compulsory system of boiler inspection, and of granting certificates of competency to those having boilers under their charge. In this we entirely agree, and we trust the time is not far distant when Parliament will establish a system of examination similar to that of marine engineers, under the control of the Board of Trade for all who have charge of stationary boilers and engines, as well as locomotives. Michael Reynolds, the author of several books on the practical working of steam-engines, has long advocated the introduction of certificates of competency for locomotive drivers and firemen. Their duties are as arduous and responsible as those of the marine engineer, and yet this fine class of men is entirely recruited from the lower grades employed in the locomotive running sheds and works, and their promotion generally depends on years of service on the footplate.

Students of steam and mechanical engineering will here find information which, although not generally taught in the lecture-rooms, will indicate some of the many points an ordinary engine-driver has to be thoroughly acquainted with. N. J. L.

The Encyclopædic Dictionary. Vol. VI. (Part II.) (London: Cassell and Co., 1887.)

THE special characteristic of this work is that the compilers have tried to make it combine some of the advantages of an encyclopædia with all the advantages of a dictionary. The result, upon the whole, is very satisfactory. The information given in the encyclopædic part of the work is not, of course, sufficient for students; but it will meet the wants of readers who may wish to obtain a concise and trustworthy account of any subject in which they happen to be interested. Special attention is devoted to the various branches of science, and scientific terms are very carefully defined and explained. So far as we have been able to test the volume of which this is the second part, we have found it in all respects equal to the preceding volumes.

A Treatise on the Principle of Sufficient Reason: a Psychological Theory of Reasoning, showing the Relativity of Thought to the Thinker, of Recognition to Cognition, the Identity of Presentation and Representation, of Perception and Apperception. By Mrs. P. F. Fitzgerald. (London: Thomas Laurie, 1887.)

THIS is neither a treatise nor has it anything particularly to do with the principle of the sufficient reason, or with the philosophical views mentioned in the second title. It is rather a kaleidoscope of phrases, original and otherwise, that have apparently from time to time touched the author's fancy, and are now vaguely but gratefully remembered to have once possessed a meaning for her. Quotations from Ouida, Plato, Lord Dundreary, and other philosophical authorities, are tossed together impartially, without apparent purpose except to fill 400 pages; and though some reference is made occasionally to opinions said to be held by the author, such reference is nearly always too vague to show what the opinions really are. Only the hard-hearted can find even amusement in the book.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

"Infusorial Earth."

THE following letter, addressed to the Secretary of the Royal Society, has been forwarded to us for publication:—

Foreign Office, October 27, 1887.

SIR,—I am directed by the Marquess of Salisbury to state to you, for the information of the President and Fellows of the

Royal Society, that Her Majesty's Consul-General at Christiania has reported that a considerable number of pits of "infusorial earth" containing 85 to 95 per cent. of silica are said to have been discovered in the neigbourhood of Stavanger.

Capital is being sought for the purpose of working the deposits, which are estimated to be capable of yielding 400,000 cubic metres of that rare product. It is affirmed that whilst the similar deposits at Lüneburg, in Hanover, are mixed with sand and gravel, those now discovered are so pure in quality as to be available for most purposes merely after desiccation.

As this discovery may possibly have a scientific interest as well as a commercial value, I am directed to convey the above information to the Royal Society.

I am, Sir, your most obedient humble servant,

T. V. LISTER.

The Secretary, Royal Society, Burlington House.

The Electrical Condition of the Peak of Teneriffe.

THE limited number of observations on atmospheric electricity which have been already made all point, with one exception, to a normal positive difference of potential between a point some few feet above the earth and the ground itself. The only notable exception to this law was found in some observations which were made on the Peak of Teneriffe about thirty years ago. Then it appeared that the condition of the Peak was constantly resinous or negative. These observations were, however, taken with a gold-leaf electrometer, and some doubt has been expressed as to whether the sign of the electricity was correctly obtained.

I therefore thought, when taking a short trip to Teneriffe, that it would be useful to examine this question by means of the improved electrical instruments now available.

Through the courtesy of the Meteorological Office I obtained the loan of a Thomson's portable electrometer, and, through the kindness of Mr. Whipple, received at Kew all necessary instruction in the use of the instrument, and special caution as to the possible difficulty of getting a good "earth" on sun-burnt lava. Any success the observations may have had is entirely due to his care and forethought.

I was only able to stay about a fortnight on the island, but the results obtained were so uniform that there can be no doubt as to their accuracy.

The height of the electrometer fuse was always about 5 feet 6 inches above the ground. At the Port of Orotava, at the base of the Peak, and about 50 feet above sea-level, the mean of eight sets of observations—each set usually consisting of six determinations—gave a potential of 138 volts. The highest was 193, and the lowest 98 volts. These, and all I obtained in Teneriffe, were uniformly positive.

One day I took a skirmishing expedition to the rock of Gayga, a portion of the rim of the old crater, 7100 feet above the sea. On the way up, while on the pretty uniform slope of the mountain, at 3800 feet, the potential was only + 99 volts, while on the rock itself, tension rose to 257 volts. The rock is a long sharp, narrow edge, perhaps half a mile long, with a precipitous cliff of 500 feet on one side. The rock was composed of dry lava, and I thought a little damp, but still the earth observations were not quite so accordant as usual.

A few days later, therefore, when starting for the top of the Peak, I took, as suggested by Mr. Whipple, an ordinary 66-foot iron surveyor's chain to be laid along the ground and connected with the instrument. The readings at different heights, on the way up, were as follows:—

At 5600 feet, on the slope of the mountain, 111 volts.

On the Cañadas, or rough flattish ground that forms the bottom of the old crater, at 5800 feet, 139 volts. The ground here was pumice and pumice dust, so I tried running out the chain to see if the earth-readings would be altered. There was not however the slightest change, and to show the character of the observations five out of the six earth-readings gave the same number.

At the *Estancia de los Ingleses*, 10,500 feet, situated on the slope of the main peak, the potential fell to 118 volts. The sun was setting, and dew falling so fast that the top of the electrometer box was covered with wet. There could be no doubt then of obtaining a good earth.

On the top of the Peak, 12,200 feet, the potential actually rose to no less than 549 volts. This was at 8 o'clock in the morning of October 24. The wind was blowing at the rate of about 10 miles an hour from the north-east, while the dry and wet bulb thermometers marked 31° and 26° respectively. There was a little white frost on the ground, and the earth-readings, without the chain, were remarkably uniform, only differing by the 11-100th of a turn of the screw.

The results of all the observations points unmistakably to the conclusion that during this month of October *the electrical condition of the Peak of Teneriffe were the same as in every other part of the world. The potential was moderately positive at the same distance from the ground even at considerable altitudes, but the tension rose enormously round a sharp point, and a projecting edge of rock.*

It is well known that there are very few thunderstorms in Teneriffe, though one passed near us at Orotava without affecting the indications of the electrometer. Would it not be interesting to measure the potential on the summit of a mountain like Kina Balu in Borneo, which is about the same height as the Peak of Teneriffe, but situated in the heart of the equatorial zone of the constant electrical discharge?

We had one day of very heavy rain, when possibly some negative indications might have been obtained; but I did not think it expedient to let the instrument get drenched.

But, besides obtaining these decisive electrical results, I was also very fortunate in some other observations during the short stay in Teneriffe.

We saw from the *Estancia* the shadow of the Peak at sunset gradually creep along the land and surrounding sea, and then stand up in the air like another peak rising above the horizon. This is what is so often seen from Adam's Peak in Ceylon, and from Pike's Peak in Colorado.

Then our observations confirmed not only the important discovery made by P. Smyth, that cloud is not formed at the junction of a south-west current flowing over a north-east trade, but the even more important fact that there is no such thing as the supposed simple return current from the equator. At Teneriffe, as in every other part of the world I have ever visited, the general circulation of the air is on a complicated screw system, the practical effect of which is that as you ascend, the wind always comes more and more from your left hand as you stand with your back to the wind. You do not come abruptly to a south-west wind over a north-east trade, but pass successively as you rise from the surface from north-east through south to south-west, and then probably to west, or even north-west.

I also made some very important observations on the local formation of halo-forming sky, and got an excellent photograph of the genesis of a cirrus cloud from a moist current rising over the Peak, but space will not allow me to explain the results in this place.

RALPH ABERCROMBY.

21 Chapel Street, London, November 7.

"Toeing" and "Heeling" at Golf.

I FEAR that "P. G. T.'s" reply to my letter on the above subject has left us very much in the same position as before. This is regrettable, as I hoped that further light would have been shed on this interesting mechanical problem. Before complying with the invitation to "think over the result of the impulsive rotation of the club-head," I considered it would be well to get some trustworthy observations on which to reason. With this object our professional, Mr. David Lowe, made twenty-seven tee shots with the driver, while I noted the effect. My instructions to him were, whether striking off the toe or the heel, to drive as truly as he could in the direction of an object selected for that purpose. The effects were as follows:—When the ball went off the heel of the club, the ball in its flight curved to the right, even though its direction commenced obliquely to the left; to this there was no exception. The opposite curve, or to the left, with only one exception, was produced by hitting off the toe. Care was taken to ascertain in each case the point of impact of the ball on the club-face.

I now instructed him to try and curve the ball to the left, striking with the heel of the club, or to "toe it off the heel," in "P. G. T.'s" words. This feat he was unable to perform, and he gave it as his opinion that it could not be done.

Now for my explanation of "toeing" and "heeling" in reply to the invitation of "P. G. T."

Everyone who has played golf is aware that the ball when cleanly struck leaves a round mark upon the face of a new club of about five-eighths of an inch in diameter. This is the measure of the elastic distortion that takes place in the ball by the

impact. The ball is *flattened* against the club-face, and is for the time prevented from revolving. To assist the grip of the club on the ball, lines are scored over the surface of the ball. Now consider the effect of the rotation of the club-head round the centre of percussion when the ball goes off the heel or the toe.

The following diagrams of a "toed" ball will best explain my meaning—

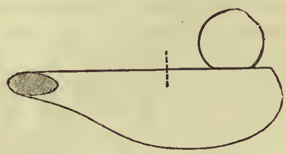

Fig. 1.

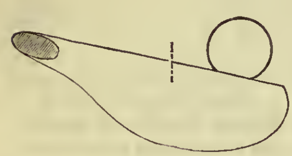

Fig. 2.

Fig. 3.

Fig. 1 shows the club-head and ball on first meeting.
Fig. 2 shows the backward revolution of the club-head due to the impact of the ball on the "toe" of the club.
Fig. 3 shows the club-head on the recovery before the ball leaves the club-face.

It is quite evident that during the movement from the position shown in Fig. 2 to that in Fig. 3 the ball, though adherent to the club-face, is revolving to the left on its own axis at the same rate as the club-head on its axis. This is the direction of spin that curves the ball to the left, or "toes" it. The opposite happens in a "heeled" ball. This rotary movement is necessarily intensified by the involuntary reaction of the wrists, which brings the club-head further round than the elastic recovery of the shaft alone would do.

I venture to think that this is the true explanation of "heeling" and "toeing." The same effects can be produced in other ways; "heeling" may be imitated by "slicing," but that does none the more make it "heeling," nor must we generalize from what happens in bad play, for then—as I know to my cost—all things are possible. T. Mellard Reade.

Park Corner, Blundellsands, October 22.

The Ffynnon Beuno and Cae Gwyn Caves.

The letter from Mr. Worthington G. Smith in the last number of Nature (p. 7) affords a remarkable instance of rushing into print and giving an opinion on a subject with which the writer is unacquainted. Speaking of the deposits in the caves, he states that all he knows about the matter has been derived from reading a very short abstract of a paper read by Dr. Hicks at the recent meeting of the British Association, in which the caves are referred to. Now, so much has been written and published on the Ffynnon Beuno and Cae Gwyn Caves in Nature and other scientific publications, that it is extraordinary that anyone should venture to offer an opinion without previously reading up the literature of the subject. Mr. Worthington G. Smith states that he has visited the caves, and is fairly well acquainted with the Glacial deposits of North Wales and with Palæolithic implements in general, and that his "unbiased opinion is, and will so remain—unless" he gets "very convincing proof to the contrary—that the drift at the caves has been without doubt relaid." We may be thankful for Mr. Smith's opinion, but unfortunately it is not worth anything, as his letter conclusively proves. Although his opinion is of no consequence, I think it should not pass unnoticed, and it affords me an opportunity of stating that during the last month the drift about the entrance of the Cae Gwyn Cave has been again carefully examined, and that the Reports of the British Association Committee have been fully confirmed. G. H. Morton.

Liverpool.

THE VICTORIA UNIVERSITY.

We are glad to observe that the application of the Yorkshire College for admission to the Victoria University has been successful. Doubt was expressed by some members of the Court as to whether the Faculty of Arts in the Leeds institution was strong enough to justify its claim to share in the privileges enjoyed by Manchester and Liverpool. This doubt was overruled. The Charter requires that the provision for teaching both arts and sciences in a College must be "reasonably sufficient" before it can be admitted to the University. It is not, however, intended that it must be equally developed in both directions. The Yorkshire College is no doubt stronger on the scientific side, and was indeed originally called the "Yorkshire College of Science." The name was changed, and the limitation it implied removed, two years after its foundation, when the Council formally took over the classes in literature and history previously carried on by the Cambridge University Extension.

The subjects of a curriculum in Arts are now taught, though the number of Professors engaged in the task is less than could be wished. The Professor of Classics is Principal, and representative of his scientific as of his Arts colleagues on the Council. There is a Professor of English Literature and History, and there are Lecturers in French, German, Italian, and some Oriental languages. An institution which provides a staff competent to teach these subjects, and places its Professor of Classics at its head, cannot be accused of an undue preference for science, and is, we think, fully qualified under the terms of the Charter.

One of the advantages of the federation of local Colleges in a University is that members of their governing bodies will be brought together in its management, and will thus learn practically what is being done in other institutions. Leeds will no doubt be stimulated to attempt to bring its Arts Faculty to the level attained by Manchester. Manchester may learn that combined classes for both sexes are practicable, and that the addition of a Faculty of Technology to those of Arts and Science may be of advantage to all concerned.

The Victoria University is now fairly started on its career, and its constituent Colleges have their future in their own hands. Manchester, Liverpool, and Leeds can confer degrees on students in their principal educational institutions untrammelled by the requirements of any external authority. We believe that this experiment is more promising than an attempt to subordinate local Colleges to our older Universities. Oxford and Cambridge have traditions and peculiarities which those who know them best would wish to survive amid the changes which are from time to time necessary to bring them into harmony with the spirit of the age. Had a close union been formed between these Universities and the local Colleges, it is probable that the Colleges would gradually have destroyed much that in its place in the Universities is useful, or that the Universities would have checked the growth of the Colleges by insisting on the attempt to fulfil conditions which in a manufacturing town are unattainable.

However this may be, it is certain that the most successful provincial Colleges have achieved success without direct connection with Oxford or Cambridge, though from the fact that graduates of these Universities are always to be found on the Professorial Staff they have exercised an indirect and no doubt useful influence.

If the Victoria University succeeds in combining the love of knowledge for its own sake with a readiness to meet the practical requirements of an age in which success in commerce and in learning are closely related, it may acquire a prestige and an authority second to that of no other educational institution in the country.

THERMO-MAGNETIC MACHINES.

IT would seem that at the present time there is being developed in the United States a new kind of engine, capable, at least in theory, of turning, by a magnetic method, the latent energy contained in fuel either into mechanical work or into the energy of electric currents. In this kind of machine the variations produced in the magnetic power of metals, such as iron and nickel, by heating and cooling them, are made the means of generating in the one case electric currents, in the other mechanical motion. The latter application was the earliest to be suggested. In the columns of NATURE (vol. xix. p. 397) will be found a note, extracted from the Journal of the Franklin Institute, upon a thermo-magnetic motor devised by Prof. E. J. Houston and Prof. E. Thomson, of Philadelphia. In this curious apparatus a disk or ring of thin steel is mounted on a vertical axis so as to be quite free to move, with its edges opposite the poles of a horse-shoe magnet. This wheel becomes of course magnetized by induction. When, however, heat is applied at a point on the circumference, the change thereby produced in the magnetic susceptibility of that part causes the disk to move round so as always to bring into line with the poles those portions of the disk which are for the time being the most susceptible to magnetization. Hence if the heating is continuous there will be a continuous rotation; the parts of the disk cooling as they leave the source of heat, and again becoming heated as they pass through the place where heat is being applied. The very same kind of thermo-magnetic motor was re-invented, in 1886, by Prof. Schwedoff, of Odessa, who, in a paper in the *Journal de Physique*, pointed out that this was a genuine case of conversion of heat into work, and gave the theory of the transformation and the cycle of operations from the thermo-dynamic point of view.

The next stage of invention in point of time, though it has only just been made public, is the suggestion by Mr. E. Berliner, of Washington, to use these thermo-magnetic variations in iron for the purpose of generating electric currents. In June 1885 Mr. Berliner filed an application for a patent for an "electric furnace generator," of which the following are the underlying principles:—"If," he says, "I take a magnet and provide it with a coil around its pole or poles, and place before this magnet and in proximity to the coil a piece of iron heated to bright red, nothing will occur to disturb the magnetic field; but the instant the iron cools down to a dull red, the magnetism becomes excited, and a momentary current of electricity is produced in the coil. I may go a step further and have a series of such magnet coils and iron armatures, and by connecting the coils into the same circuit, and cooling the armatures in rotation one after the other, a number of electrical impulses will be produced, which, when they follow one another rapidly, will approximate to a continuous electric current. . . . The current thereby produced might be utilized to charge another coil surrounding the magnet and reinforce the field; and in that case the magnet might be substituted by a tubular core of iron, . . . or a series of coils and magnets might be placed toward one larger armature disk, forming a common armature, heated by one furnace."

The most recent suggestions in this line come from Mr. T. A. Edison, who, independently of Mr. Berliner, has devised an almost identical generator, to which he has given the name of a "pyro-magnetic dynamo." At the recent meeting of the American Association of Science, a paper by Mr. Edison, giving an account of his machines, was read, and has been largely noticed in the non-technical press, as though it were an absolutely new departure in electric science. The famous inventor may certainly lay claim to having worked out in greater detail the practical problems of construction. In the generator there are eight double-pole electro-magnets arranged radially. At the top the eight poles converge toward a central space; and about a foot below the other eight poles converge toward a second central space. In these central spaces lie two soft iron disks, forming the cheeks of the armature, and pierced with eight large holes, each to receive eight vertical armature cores, each of which consists of a roll of corrugated sheet-iron surrounded with a coil of wire insulated with asbestos. The eight wire coils are connected up together and joined to a commutator, just like the coils in the armature of Niaudet's dynamo. This armature stands over a furnace, the heated gases of which are led up through the interstices of the eight rolls of sheet-iron. By the use, however, of a revolving screen of fire-clay the ascending hot gases are cut off successively from some of these tubular cores so that they are alternately heated and cooled, giving rise to electric currents in the coils, which currents are collected above by the action of the commutator. The arrangement appears to have been constructed with Mr. Edison's well-known ingenuity. The inventor has also constructed a pyro-magnetic motor, which consists essentially of a powerful field-magnet (independently excited) having between its poles as a rotating armature a bundle of small vertical tubes of very thin iron, which are packed in a convenient drum-like form and mounted on a vertical spindle. From a furnace underneath rise currents of heated air, and pass through the iron tubes; but, by a screen placed in a suitable position below, the heated air is prevented from rising through some of the tubes, and instead thereof a blast of cool air is blown down these: the cooled tubes, becoming more highly magnetic, are more powerfully attracted by the poles of the field-magnet, and move forward, only to be afresh heated, whilst a new set of tubes comes into position to be cooled and attracted. Mr. Edison states that already a speed of 120 revolutions per minute is practicable; and he is building one of these motors calculated to work at 3 horse-power. Whether the sanguine hopes which he expresses as to the economic working of such motors and generators, as compared with existing engines and dynamos, will be fulfilled in the future is as yet a matter of speculation. But the practical problem, even though it is surrounded by many obvious difficulties, is of so tempting a nature, and the attempt to solve it is so daring, that we must wish to our Transatlantic friends the utmost success in their efforts to supersede the present wasteful methods of utilizing the latent energy of fuel.

NOTES.

THE following is the list of names recommended by the President and Council of the Royal Society for election into the Council for the year 1888, at the forthcoming anniversary meeting on the 30th inst.:—President: Prof. George Gabriel Stokes. Treasurer: Dr. John Evans. Secretaries: Prof. Michael Foster, the Lord Rayleigh. Foreign Secretary: Prof. Alexander William Williamson. Other members of the Council: Sir William Bowman, Bart., Henry Bowman Brady, Prof. Arthur Cayley, W. T. Thiselton Dyer, Prof. David Ferrier, Dr. Edward Frankland, Dr. Arthur Gamgee, Prof. Joseph Henry Gilbert, Prof. John W. Judd, Prof. Herbert McLeod, Dr. William Pole, William Henry Preece, Admiral Sir George Henry Richards, K.C.B., Prof. Arthur William Rücker, the Earl of Rosse, and Sir Bernhard Samuelson, Bart.

MR. F. J. JACKSON has presented to the Natural History Museum an interesting set of animals collected by him during his three years' residence in East Africa. The birds are particularly valuable, and contain many species new to the Museum collection. Mr. Jackson resided for some time in the Kilima N'jaro district, and procured several rare species hitherto only known from the late Dr. Fischer's collections in the Berlin

Museum. From Lamu and Manda Island the additions to the Museum collection are numerous, and supply many desiderata to the series of bird-skins.

THE remains of the great naturalist, Audubon, lie in an obscure and little-visited portion of Trinity Cemetery, New York City, and his tomb is not marked by any distinguishing monument. A movement has been started for the erection of a suitable monument. At the first autumn meeting of the New York Academy of Sciences a Committee was appointed to collect funds and make all necessary arrangements. This Committee, of which Dr. Britten is Secretary and Treasurer, is now ready to receive subscriptions, which will be properly acknowledged. It is estimated that from 6000 to 10,000 dollars will be required. While confident that this amount might be collected in America, the Committee are anxious that interest should be taken in the project by men of science in all departments in all parts of the world.

MR. EDWIN LEES, who died lately at Worcester at the age of eighty-seven, had a considerable reputation as a naturalist. Among his writings are "The Botany of the Malvern Hills," "Pictures of Nature among the Malvern Hills and Vale of Severn," "The Botany of Worcestershire," and "The Forest and Chace of Malvern." He was one of the founders of the Worcestershire Natural History Society, and of the Worcestershire Naturalists' Field Club.

MR. THOMAS BOLTON, of the Microscopists' and Naturalists' Studio, Birmingham, died on Monday. He was in his fifty-seventh year. About a year ago a Civil List pension of £50 per annum was granted to Mr. Bolton in recognition of his services as a naturalist and microscopist. The memorial setting forth his claims, discoveries, and special circumstances was signed by Sir J. W. Dawson and many other eminent men of science.

A CONFERENCE on Technical Education, in which working men took a prominent part, was held last Saturday evening at the Finsbury Technical College. There was a large attendance of students and others. Mr. James Rowlands, M.P., occupied the chair, and Prof. Silvanus P. Thompson read an address on "The Present Position of the Technical Instruction Question." Prof. Thompson urged that the most essential of all the conditions for the organization of an adequate system of technical instruction is the creation of "a real Education Department under a real Minister of Education."

AT the annual meeting of the delegates of the Union of Lancashire and Cheshire Institutes at Crewe on Monday, Lord Derby delivered an excellent address on education. In the course of his remarks he pointed out that the "Institutes of fifty years ago for the most part failed because of the want of good primary schools to feed them. "You have the schools now," he continued, "and what we have to do is to provide the means of carrying on the instruction of those who are willing to learn after the time when they are clear of school, and free to follow their own devices when the day's work is over." Speaking of technical instruction, Lord Derby said :—" We are fighting for the markets of the world ; we have held our own hitherto, but the struggle is sharper than ever, and we cannot afford to throw away any advantage which is possessed by other countries. It may be that, as often happens, we shall find out that we have overrated the benefit of technical teaching, that it can do less for us than we now expect ; but we are not the less bound to try, and to deserve success, whether we get it or not."

SOME electric balloon signalling experiments were carried on at Berchem, in the fortifications outside Antwerp on Wednesday evening, October 26. The system used was known as the Bruce system, and the inventor, Mr. Eric Stuart Bruce, himself superintended the experiments at the invitation of the Belgian War Minister. The balloon used, which had just been purchased of Mr. Bruce by the Belgian Government, was a small one, being only 15 feet in diameter. It had been designed for hydrogen, but though it was filled with very dense coal-gas it lifted 500 feet of electric cable besides its captive rope. This special cable was an improvement on what was formerly used by Mr. Bruce, being now lighter though of the same current capacity. The Bruce key also, which gave great satisfaction, has been lately considerably modified, and can carry any current, the contacts being of carbon, which can easily be renewed on wearing away. The Minister of War, General Pontus, General Wauwermans, Inspector-General of Fortifications at Antwerp, and various other distinguished officers were present, including special delegates from Russia, Holland, &c., &c. The first telegram sent was : "Porte d'Herenthals de Berchem. Voyez vous distinctement signaux Bruce, répétez la dépêche par téléphone. (Signé) Général Wauwermans." This was distinctly read and telephoned back. Also the second, sent by the Minister of War : "Envoyez un bataillon au fort I. (Signé) Ministre Guerre Pontus." A third telegram sent to the Caserne of Telegraphists was equally successful. There were six lights in the balloon giving about twenty candle-power each. The telephonic stations of Rehls were comparatively near, being only at a distance of from 4 to 5 kilometres ; the object that night being to test at once the distinctness of the signals, by placing the observing-stations on the existing telephonic circuits ; but the night was an ideal one for signalling, and it is understood that the balloon was seen to an enormous distance. A company was also on the look-out at the top of the tower of Notre Dame, at Antwerp (4 kilometres), and they distinctly read all the messages sent.

CONSIDERABLE uncertainty has, up to the present time, existed as to the number and composition of the compounds of gold with sulphur. For years it was supposed that there were three sulphides of gold—Au_2S, Au_2S_2, and Au_2S_3 ; but Schrötter and Pruvoznik, in 1874, came to the conclusion that no sulphides of gold were to be obtained in a pure state, thus leaving the subject in greater darkness than ever. Happily, however, this deplorable uncertainty has at length been completely dispelled by Drs. Hoffmann and Krüss, of Munich, who have abandoned the methods of Berzelius, Levol, and Schrötter and Pruvoznik, for more fruitful ones of their own. The lowest sulphide of gold, Au_2S, was obtained by the addition of hydrochloric acid to a solution of the double cyanide of gold and potassium saturated with sulphuretted hydrogen. The last traces of admixed sulphur were removed by washing with sulphuretted hydrogen solution, alcohol, ether, carbon disulphide, and finally again with ether. After drying over phosphoric oxide, pure Au_2S was obtained as a dark-brown powder, yielding theoretical numbers on analysis. When freshly precipitated it is remarkably soluble in water, indicating a close relationship to the metals of the alkalies, whose sulphides are also soluble in water, and thus asserting its position in the first vertical series of the periodic system. With polysulphides of the alkalies it forms green sulpho-salts. It decomposes at 240°, leaving a residue of pure gold, and, if warmed in a stream of oxygen, takes fire, forming SO_2, and again leaving its gold in the metallic state. In a second communication in the current number of the *Berichte*, Hoffmann and Krüss describe how they have succeeded in preparing Au_2S_2. A cold neutral solution of gold chloride was precipitated by sulphuretted hydrogen until the supernatant liquid became colourless. Admixed sulphur was removed from the precipitate in a manner similar to that employed in case of Au_2S, and finally pure Au_2S_2 isolated as a deep black substance, decomposed by heat similarly to Au_2S. It is distinguished from the latter sulphide by being decomposed by caustic potash with formation of potassium oxy- and sulpho-salts and separation of a little metallic gold. Au_2S_3 of Berzelius was found not to

exist, being merely a mixture of Au_2S_2 and sulphur, for the former substance was completely extracted by a solution of potassium cyanide, leaving an emulsion of finely-divided sulphur.

THE November Bulletin of Miscellaneous Information, issued from the Royal Gardens, Kew, is the first of a series of papers in which information will be given as to the capabilities of our colonies to grow and export fruit. The authorities of Kew have little doubt that, if proper arrangements were made for packing and shipping, large quantities of fruit might be exported from Cape Colony, Natal, the Australian colonies, and New Zealand. It is thought that much of this, arriving in England during the winter and early spring months, would be readily bought to supply the wants of the community, and that the prices paid for such fruit as an article of luxury would be sufficiently high to cover the cost of bringing it from the southern hemisphere. Much interest was taken in the fruit shown from all parts of the Empire at the late Colonial and Indian Exhibition. An effort, therefore, has been made at Kew to collect information on the subject, and excellent service, no doubt, will be done by the publication of the facts which have been brought together. In the present Bulletin a full account is given of Canadian fruits.

THE fifth part (just issued) of the Transactions of the Leicester Literary and Philosophical Society contains an interesting paper, by Mr. F. T. Mott, on foreign fruits available for acclimatization in England. Among the plants to which he calls attention is the *Zizyphus vulgaris*, which produces a yellow fruit of pleasant flavour, the size of a small gooseberry. These fruits are usually dried and sold under the name of jujubes, the gelatine jujubes of our shops being named after them. "It is probable," says Mr. Mott, "that no species of *Zizyphus* in its present condition would ripen its fruit in English gardens, but the art of cultivation consists in so modifying the natural habits of plants as to adapt them to man's needs in various climates. This is accomplished by selection, propagation by seed, changes of soil, and gradual exposure. The first step would probably be to obtain a hardy variety of the *Zizyphus vulgaris* regardless of the quality of the fruit. A tree should be selected in the most elevated and exposed situation in which it naturally ripens its fruit. Seeds from this tree should be grown in a slightly colder climate, and if any of them can be got to ripen fruit, the seeds of these should be again reared still further north. In this manner the tree might gradually be acclimatized in our southern counties. Having once obtained a sufficiently hardy stock, the next process would be to improve the fruit. This would be done by selection of seed with reference to the fruit rather than to the hardiness of the plant, by crossing with Indian or Chinese species, and by careful study of soil and general treatment. The process of thus producing a new hardy fruit would be tedious, because fruiting trees can scarcely be brought to such a state of maturity as to show their true characters in less than eight or ten years from the sowing of the seed, and five or six generations at least might be required to produce any useful result. But the experiment would be interesting in all its stages, and the object if ultimately attained would be of great value."

WE have received the General Report on the operations of the Survey of India Department, administered under the Government of India, during 1885–86. The Report has been prepared under the direction of Colonel H. R. Thuillier, R.E., officiating Surveyor-General of India. It is divided into three parts. Part I. is introductory; Part II. contains a summary of the operations of the trigonometrical, topographical, and revenue survey parties; in Part III. there is an account of the operations of the several head-quarter offices. Extracts from narrative reports are presented in an appendix. Among the "general remarks" in Part I. there is a paragraph in which some dissatisfaction is expressed with existing arrangements. "The large demands," says the writer, "that have been made on the Survey Department for officers required to accompany political missions and military expeditions, and for other special work, combined with the circumstance of a larger percentage than usual being absent on medical leave, has rendered the efficient prosecution of the regular work of the Department peculiarly difficult. This has been the subject of remark in the Annual Reports for the past two years, and during the year under review the paucity of officers has been still more seriously felt. There has been absolutely no reserve of trained officers, and the administration of the Department has consequently been a task of considerable anxiety. It is necessary to record that the working machinery of the Department has been limited to a dangerous extent."

IT is stated that the Government of the Straits Settlements are about to undertake a systematic survey, on the Indian plan, of their territory and of that of the neighbouring "protected" States. Colonel Burrow, of the Indian Survey Department, was recently appointed to advise the Colonial Government on the subject, with the result here stated.

THE Asiatic Society of Japan has, we are glad to observe, published a General Index to its Transactions. There are now thirty-six parts, or fifteen volumes, of the latter, and as almost every foreign scholar in Japan has been a contributor to the Society's Proceedings for fourteen or fifteen years past, it was necessary that an index should be published. About two years ago we noticed the publication of an index to the Proceedings of the Society's friendly rival, the German Society.

MR. HENRY SEEBOHM is about to issue a work on the Geographical Distribution of the *Charadriidæ* (Plovers, Sandpipers, and Snipes, &c.). The unrivalled collection of Wading Birds in Mr. Seebohm's possession supplies the material for this work, and the volume will undoubtedly be one of great interest to ornithologists. Mr. Seebohm's ideas on nomenclature, the influence of the Glacial epoch on the migration of birds, and other kindred subjects, are always original, and this new work of his will open, according to the prospectus, with an introduction setting forth his latest opinions. There is also to be given "a complete synonymy from 1776 to the present time," a rather appalling announcement, and one involving a vast change in ornithological nomenclature, as it will preclude the use of Linnean names.

A TRANSLATION, by Miss Margaret K. Smith, of Seidel's "Industrial Instruction" is about to be issued in America by Messrs. D. C. Heath and Co. The author presents an exposition of "the principles underlying the claims of hand labour to a place on the school programme."

"THE Shell-Collector's Hand-book for the Field," by Dr. J. W. Williams, the editor of *The Naturalist's Monthly*, will be published immediately by Messrs. Roper and Drowley. It will give full directions as to the collecting and preserving of British land and fresh-water shells, and will describe the habitat of each. Every genus, species, and variety known to the Conchological Society up to date of publication will be noted.

MR. T. A. WALKER'S "History of the Making of the Severn Tunnel" is, we understand, likely to appear about Christmas. In addition to portraits on steel of some of the more prominent engineers concerned in the enterprise, there will be numerous plans and sections showing the gradual progress of the work, and diagrams of the large pumping-engines, &c. Messrs. Bentley and Son will be the publishers.

SIR JAMES PAGET'S address to the medical students at Owens College, delivered at the opening of the session 1887–88, has been published. The subject is, the utility of scientific work in the practice of medicine and surgery.

THE new number of the Journal of the Anthropological Institute contains a striking paper by Dr. George Harley, in which he attempts to show that the tendency of civilization is decidedly to lower the bodily recuperative powers of human beings. Another interesting paper—by Mr. G. L. Gomme—is on the evidence for Mr. McLennan's theory of the primitive human horde.

MESSRS. S. WIGG AND SON, Adelaide, are issuing a work on "Common Native Insects of South Australia," by Mr. J. G. O. Tepper. It is intended to serve as a popular guide to South Australian entomology. Part I. relates to Coleoptera.

A PAPER containing a list of the mammals of Manitoba, by Mr. Ernest E. Thompson, has been reprinted from the Transactions of the Manitoba Scientific and Historical Society. It consists chiefly of the author's field notes.

A CORRESPONDENT writes from St. Petersburg that tigers have been encountered this autumn in parts of Asiatic and European Russia where they have never been found before. Some time ago one of these beasts was captured near Wladiwostock, in Siberia, and another in the government of the Caucasus, close to the Black Sea. Both animals have been conveyed to St. Petersburg alive.

A NORWEGIAN astronomer has collected seventeen reports from various parts of Norway respecting the great meteor seen in that country on the evening of September 18, no doubt the largest meteor seen in Norway in recent times. These reports show that the meteor was seen as far north as Hamar, in Central Norway, and as far south as the towns of Fredrikshald and Skien, on opposite sides of the Christiania Fjord, the capital and neighbourhood appearing to be in the centre of its track. Its light was everywhere magnificent, having the appearance of a sudden blaze of electric light. The reports from Drammen and neighbourhood, as well as those from the province of Smaalenene, on the opposite side of the Christiania Fjord, maintain that the bursting of the meteor, which took place within this area, was accompanied by a loud report; but the astronomer in question is of opinion that this belief is due to some freak of the imagination, as the track of the meteor, covering such a vast area of land, must have lain too high in the atmosphere for any sound to be heard. He calculates from the reports to hand that the bursting of the meteor occurred at an altitude of about 6000 feet, and he thinks that even this figure may be safely doubled, as no doubt the meteor was seen far north and south of the places whence reports have been received.

THE Aino idea of an eclipse is described by the well-known student of Aino language and manners, Mr. Bachelor, in a recent number of the *Japan Weekly Mail.* Mr. Bachelor specially observed the conduct of the Ainos during the recent eclipse. The Aino, he says, is a very matter-of-fact person, and is not usually carried away by the imagination. On being shown the eclipse through a smoked glass, the Aino cried out that the sun was fainting away and dying. A silence then ensued, and from time to time an exclamation of surprise or fear was to be heard; it was evident the fear was that the sun would die away and never revive. They brought water and sprinkled it upwards towards the sun (as they would do if a human being were expiring), crying at the same time, "O god, we revive thee! O god, we revive thee!" Some squirted the water upwards with their mouths, others threw it with their hands, others, again, used the common besom or willow-branches, the latter being supposed to be specially efficacious. A few, especially women and girls, sat down with their heads hidden between their knees, as if silently expecting some dreadful calamity to suddenly befall them. They have no theories with regard to eclipses, but their traditions run like this:—"When my father was a child, he heard his old grandfather say that his grandfather saw a total eclipse of the sun. The earth became quite dark, and shadows could not be seen; the birds went to roost, and the dogs began to howl. The black, dead sun shot out tongues of fire and lightning from its sides, and the stars shone brightly. Then the sun began to return to life, and the faces of the people wore an aspect of death; and, as the sun gradually came to life, then men began to live again."

THE first meeting of the one hundred and thirty-fourth session of the Society of Arts will be held on Wednesday, November 16, when the opening address will be delivered by Sir Douglas Galton, Chairman of the Council. Previous to Christmas there will be four ordinary meetings, in addition to the opening meeting. For these meetings the following arrangements have been made:—November 23, Prof. Silvanus P. Thompson, "The Mercurial Air-pump;" November 30, Mr. J. B. Hannay, "Economical Illumination from Waste Oils;" December 7, Mr. P. L. Simmonds, "The Chemistry, Commerce, and Uses of Eggs of Various Kinds;" December 14, Sir Philip Magnus, "Commercial Education." During the session there will be six courses of Cantor Lectures—"The Elements of Architectural Design," by Mr. H. H. Statham; "Yeast, its Morphology and Culture," by Mr. A. Gordon Salamon; "The Modern Microscope" (being a continuation of the recent course of Cantor Lectures on the "Microscope"), by Mr. John Mayall, Jun.; "Alloys," by Prof. W. Chandler Roberts-Austen, F.R.S.; "Milk Supply and Butter and Cheese Making," by Mr. Richard Bannister; "The Decoration and Illustration of Books," by Mr. Walter Crane. Two juvenile lectures on "The Application of Electricity to Lighting and Working," by Mr. William Henry Preece, F.R.S., will be given during the Christmas holidays.

THE additions to the Zoological Society's Gardens during the past week include a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, presented by Mr. E. B. Mitford; a Weeper Capuchin (*Cebus capucinus*) from Brazil, presented by Mr. C. N. Skeffington; a Raccoon-like Dog (*Canis procynides*) from China, presented by Mr. W. T. Manger; an Indian Antelope (*Antilope cervicapra*) from India, presented by Mrs. M. V. Charrington; a Leopard (*Felis pardus*) from Ceylon, presented by the Dissawe of Tamankadua Dulewa Adijur; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mr. A. Townsend; a Naked-footed Owlet (*Athene noctua*), European, presented by Mr. R. E. Holding; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mr. G. E. Frodsham; two Larger Hill-Mynahs (*Gracula intermedia*) from Northern India, presented respectively by Mr. J. M. Cook and Mrs. J. S. Beale; a Gray-headed Porphyrio (*Porphyrio poliocephalus*) from India, presented by Lady Morshed; a West African Python (*Python sebæ*) from West Africa, a Common Boa (*Boa constrictor*) from South America, two Testaceous Snakes (*Ptyas testacea*), an Alleghany Snake (*Coluber alleghaniensis*) from North America, deposited; six Mocassin Snakes (*Tripidonotus fasciatus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE VARIABLE STAR U OPHIUCHI.—Mr. S. C. Chandler, Jun., who first determined the true period of this star, of all variables the one with shortest period and most rapid fluctuations of light, has brought together, in No. 161 of *Gould's Astronomical Journal*, all the observations of magnitude of this star available. Of these, one made by Schjellerup on June 7, 1863, is of special value, as it was evidently made near the time of minimum, and at an interval of nearly 8000 periods from the principal epoch; whilst a series made at Cordoba in 1871 and 1872 has proved of very high importance. The discussion of these various observations show that it is exceedingly probable that the period has undergone a slight shortening; all the data being well reconciled by the assumption that each period is

shorter than the preceding one by 0·0004s. The corrected elements of the star will therefore be as follows:—

1884 January 1, 0h. 54m. 43·6s. Paris M.T. + 20h. 7m. 41·6s. (E – 1070) – 0·0002s. E.

THE NEW ALGOL-VARIABLE, Y CYGNI.—In the same number of *Gould's Astronomical Journal* Mr. Sawyer states that he has obtained observations of this star which render it probable that the true period is 1d. 12h. ±, or half the period which Mr. Chandler had adopted for it (see NATURE, vol. xxxvi. p. 377).

OLBERS' COMET, 1887.—The following ephemeris is in continuation of that given in NATURE, vol. xxxvi. p. 588:—

Ephemeris for Berlin Midnight.

1887.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
Nov. 11	14 24 15	13 59·0 N.	0·1152	0·3037	1·20

GEOGRAPHICAL NOTES.

THE November number of the *Scottish Geographical Magazine* contains an admirable paper by Mr. John Murray, on "Some Recent Deep-sea Observations in the Indian Ocean." Mr. W. W. Blair, C.E., contributes a useful paper on the "Cold Lakes of New Zealand." Prof. Mohn sends a list of the highest peaks in Northern Europe, with their heights from the latest determinations. They are, with heights in feet:—Galdhoppigen, South Norway, 8399; Glitter Tind, 8379; Snehætten, 7566; Oræfajökull, 6427; Sulitelma, Northern Norway, 6178; Petermann's Spitze, East Greenland, 11,418; Beerenberg, Jan Mayen, 8350; Mount Misery, Bear Island, 1785; Hornsund Tind, Spitzbergen, 4560; Richthofen Mount, Franz Josef Land, 5184. Of these mountains two are volcanic, Oræfajökull and Beerenberg.

THE new number (9) of the *Mittheilungen* of the Vienna Geographical Society contains a summary of our knowledge of the physical geography of the East Asiatic waters (the Western Pacific and its offshoots)—currents, temperatures, &c.—by Lieut. Adolf Glockner.

IN the September number of the *Bulletin* of the American Geographical Society, Mr. R. E. Peary gives a detailed account of his journey, in the summer and autumn of last year, into the interior of Greenland. He entered in the neighbourhood of Disco Island, considerably further north than the starting-point chosen by Nordenskjöld for his expedition. Mr. Peary's experiences were somewhat similar to those of Nordenskjöld. His course throughout the journey was due east. He only reached 100 miles from the edge of the ice-blink or interior ice, his highest elevation being 7525 feet. Mr. Peary sums up his observations of the character of the interior ice. The coast-line shows a great diversity of features, dependent upon the altitude, the season, and the elevation and configuration of the adjacent mountains. Whenever the ice projects down a valley in a long tongue or stream, the edges contract and shrink away from the warmer rocks on each side, leaving a deep cañon between, usually occupied by a glacier; and the upper surfaces, disintegrated by the reflected heat from the mountains above, and shattered by the daily change of temperature more perhaps than by the forward flow, presents a chaotic labyrinth of crevasses, gullies, and rugged pinnacles, increasing in magnitude in direct proportion to the length of the tongue and its approach to the sea-level. As to the features of the interior beyond the coast-line, the surface of the "ice-blink" near the margin is a succession of rounded hummocks, steepest and highest on their landward sides, which are sometimes precipitous. Further in these hummocks merge into long flat swells, which in turn decrease in height towards the interior, until at last a flat gently rising plain is reached, which doubtless becomes ultimately level. In passing from the margin of the ice-blink to the remote interior, from one to five distinct zones may be noted, the number and width varying with the season, the latitude, and the elevation. In winter the entire surface is undoubtedly covered with a deep unbroken layer of fine dry snow. Late in the spring the warmth of the sun at midday softens the surface of the snow, along the land borders of the ice, and this freezes at night, forming a light crust. Gradually this crust extends up the interior, and with the advance of the season the snow along the border of the "ice-blink" becomes saturated with water. A little later the zone of slush follows the zone of crust into the interior, the snow along the border of the ice-blink melts entirely, forming pools in the depressions, and streams which cut deep gullies in the ice; water-cavities form; old crevasses open, and new ones appear. This zone rapidly widens, and extends into the interior in the footsteps of the others, and behind it the immediate border of the ice gets ragged and soiled; pebbles, boulders, and moraines crop out of its melting surface, and by the end of the Arctic summer it is disintegrated and shattered by the heat, and eroded by the streams, into impassable roughness. Mr. Peary

gives some useful hints as to the best modes of travel over the ice, which, if followed, he believes would without any difficulty take the explorer to the east coast.

IN Heft 3 of this year's *Deutsche Geographische Blätter* will be found the first part of a detailed study of the Schwarzwald by Prof. Platz, of Carlsruhe. It deals with the orography and geology.

THE Portuguese explorer, Josè Anchieta, is at present in the Quinsumbo region of the Portuguese West African territory, on his way to Bihé. He intends to investigate the flora of the region, which has never been adequately studied.

IN the Danish Budget for 1888–89 a sum of 68,000 kroner has been allotted for research in Icelandic waters. Several large fjords of great commercial importance are entirely unexplored, and are therefore full of danger to navigation. The fishery grounds around the various islands will also be investigated. This exploration will have great interest for science, as it is likely to accumulate much valuable information in oceanography, as well as zoology and meteorology. The work will be carried on freely from May to August, and it is hoped will be completed in five or six years.

THE Roman Catholic missionaries on Yule Island have been exploring the region of New Guinea opposite their station. They found that the Ethel and Helida are insignificant streams; but they discovered a new river, the St. Joseph, which rises at the foot of Mount Yule in 8° 15′ S. lat. and 146° 40′ E., and which flows in a southerly direction. The land on both sides is highly fertile and the natives peaceful. They visited fifteen villages, several with a population of over 2000.

IN a paper in the last-issued *Bulletin* (vol. ii. No. 6) of the Californian Academy of Sciences, Mr. George Davidson gives some interesting information on submarine valleys off the Pacific coast of the United States. He points out that within 40 or 50 miles of the coast to the south of Cape Mendocino the plateau of the Pacific reaches a depth of 2000 to 2400 fathoms. Generally there is a marginal plateau for 10 miles out to the 100-fathom curve, and then the descent is sharp to 500 or 600 fathoms. In this marginal plateau there has been discovered by the Coast Survey several remarkable submarine valleys. Notably that in Monterey Bay, heading to the low lands at the great bend of Salinas River; and that off Point Hueneme at the eastern entrance of the Santa Barbara Channel, and heading into the low coast at the wide opening of the Santa Clara Valley. Then there are one or two off the southern point of Carmel Bay, while the deepest one enters far into the bay. The latest discovered submarine valleys are near the high bold coast under Cape Mendocino. Just north of a submarine ridge extending from Point Delgada to Shelter Cove is a deep valley which breaks through the marginal plateau and runs sharply into the immediate coast-line under the culminating point of the crest-line of mountains. The head of this submarine valley is 100 fathoms deep at 1¼ mile from shore; when it breaks through the 100-fathom line of the marginal plateau it reaches a depth of 400 fathoms. The slopes of the valley are very steep. Midway between this and Point Garda there is another valley 300 to 150 fathoms deep. The opening of this valley through the outer edge of the 100-fathom plateau is 520 fathoms deep. Between Point Garda and Cape Mendocino is another valley, which, 6½ miles south-west by south from the cape, is 450 fathoms deep. This is a wide valley, the bottom of which is green mud, though in two places, at depths of 320 fathoms, broken shells were brought up with gravel.

BY the latest communication from Mr. Stanley's expedition it is evident that, unless some unexpected disaster has happened, he reached Emin Pasha some time in August. He found the Mabodi country, through which the Aruwimi flows, densely inhabited, while that river on the borders of the Mabodi country bends south, and again becomes navigable. This seems clearly to show that the Aruwimi can have no connection with the Wellé system.

THE last number of the *Izvestia* of the Russian Geographical Society (1887, 3rd fascicule) will be most welcome to geographers. It contains a preliminary map (70 miles to an inch) of the eastern parts of East Turkestan, Tsaidam, and the upper parts of the Yellow and Blue Rivers, embodying the results of the fourth journey of General Przewalski in Central Asia. The most interesting feature of the map is that it shows that the depression of the Lob-nor must not be confounded with the Eastern Gobi. This last is more elevated, and falls by a steep terrace towards the depression of the Lob nor, which has in the east of the lake a width of only 80 miles, and terminates at Lake Tchin-jen-he, where the desert reaches altitudes of 3700 and 4800 feet above the sea. The Tarim depression is thus well limited in the east, and the doubts which arose among geographers as to the possibility of embodying the Eastern Gobi and the Tarim depression under the same denomination of Hang-hai, as proposed by Richthofen, are thus settled. The well-known difference of characters of the two regions depends upon the differences of their orographical structures, and the Tarim region appears as a depression of the high plateau of East Asia, limited in the east as well as in the north, the west, and the south. Geographers will find on the map the series of chains named after Colombus, Marco Polo, Humboldt, and Ritter, discovered by General Przewalski; the high range to which the Russian Geographical Society gave the name of its Russian discoverer; the Burkhanbuda range; the lakes Jarin and Orin, 14,000 feet high, of the upper Hoang-ho; and all those minor features which, when mentioned in M. Przewalski's letters, excited so much interest among geographers. A list of sixteen places, the latitudes and partly the longitudes of which have been determined, and a list of ninety-five altitudes, accompany the map.

IN a short note accompanying the above map, General Przewalski mentions certain facts brought to light during the last three months of his journey. The Khotan-daria of East Turkestan does not make a bend towards the west, as shown on several recent maps. It flows due north through a sandy desert, and its course on Klaproth's and D'Anville's maps was more in accordance with reality than the indications on more modern maps. Its water reaches the Tarim only during the summer. A new oasis, Tavek-kel, grew up some fifty years ago on the Yurun-kash; its population numbers about 500 families. The lake Yashil-kul does not exist where it is shown on our maps. The most important statement is, however, the following. By the beginning of October 1885—that is, at low water—the Tarim had, at the confluence of the Yarkand and Khotan Rivers, a depth of 3 to 5 feet, and a width of about 185 yards. In the summer, according to information obtained from the natives, and confirmed by the state of the river-bed, the depth and width of the Tarim are thrice the above. Taking into consideration the fact that the lower Tarim, followed by M. Przewalski in 1876 and 1877, has throughout a depth of no less than 14 feet, it may be maintained, M. Przewalski writes, that the Tarim is navigable for steamers on its whole length from the above junction to the Lob-nor. It seems probable also that steamers may be able to ascend a short distance up the Aksu River and further up the Yarkand-daria.

THE same number of the *Izvestia* contains an elaborate paper by M. A. Eliséeff embodying the ethnological results of his journeys in Asia Minor since 1881. In this paper there are able descriptions of the various populations of Asia Minor—the Turks, the Armenians, the Kurds, the Kurmanjis, the Greeks, the Arabs, the Chaldæans, the Tsiganes, and the Jews. The numerous anthropological measurements and other observations which the author made during his journeys in the interior of the country will be published separately in full. Two papers, on the Manych and the steppes of Northern Caucasus, by D. Ivanoff, and on the vegetation and geology of the same, by W. Fausek, are valuable contributions towards a better knowledge of the nature of this interesting region.

METEOROLOGICAL NOTES.

Symons's Monthly Meteorological Magazine for October contains a fifth annual table of the climate of the British Empire, giving a summary of the daily observations at sixteen stations, distributed over the globe, for the year 1886. The extremes show some very interesting facts, from which we select the following:—Adelaide has the highest maximum temperature in the shade, viz. 112°·4; the highest temperature in the sun, 174°·5; the least rainfall, 14·42 inches; and the lowest humidity, 56 per cent. Winnipeg has the lowest shade temperature, −44°·6; the greatest annual range, 147°·6; and the lowest mean daily temperature, 33°·2. Colombo (Ceylon) has the highest mean daily temperature, 81°·0. Bombay has the greatest rainfall, 99·74 inches. London occupies the unenviable position of the dampest station, 80 per cent. The same magazine contains a discussion of the severe thunderstorm which visited London on

August 17. The greatest rainfall on this occasion was 2·08 inches at Wimbledon, and the least at Hackney, 0·27 inch. In connection with the climatology of the British Empire, it may not be generally known that the Annual Reports of the Army Medical Department contain meteorological summaries for a number of stations mostly in the northern hemisphere, *e.g.* the Mediterranean, Africa (including Egypt), and the East and West Indies. The last Report published is for the year 1885, and contains the results of observations and the extremes from nineteen stations.

IT is stated in the *Meteorologische Zeitschrift* for October that a new edition of Prof. H. Mohn's "Grundzüge der Meteorologie" has just been published by Reimer and Co., of Berlin. The fact that the work has reached a fourth edition in twelve years shows the favour with which it has been generally received. The plan remains the same as before, but both the text and the plates have been corrected to correspond to the recent progress of the science.

MR. H. ALLEN HAZEN has contributed an article to the *American Journal of Science* for October on the relation between wind-velocity and pressure, giving a summary of the better class of experiments, the methods employed, and the results arrived at, from those of Borda, in 1763, to the present time. The methods of investigation generally adopted are (1) carrying a plate either in a straight line or in a circle; and (2) allowing a current of air to impinge normally upon the plate. The results of Borda's observations are expressed in the formula—

$$p = (\cdot0031 + \cdot00035c)sv^2,$$

in which p = pressure in pounds; c = contour of plate in feet; s = surface in square feet; and v = velocity in miles per hour. In some careful experiments made at Washington in 1866, the formula obtained, viz.

$$p = (\cdot0032 + \cdot00034c)sv^2,$$

shows a remarkable and unexpected coincidence with Borda's results, with an entirely different apparatus. By far the most careful experiments with a whirling machine were those of Hagen, in 1873, with plates varying in size from 4 to 40 square inches in area. His formula is—

$$p = (\cdot0029 + \cdot00014c)sv^2;$$

and these results have been used by Prof. W. Ferrel in his recent discussion of this question. Various other experiments are discussed, including those lately made in France on a train running at increasing velocities, which give the formula—

$$p = \cdot000535sv^2.$$

The author expresses the opinion that further experiments are much needed, with larger plates than 2 feet square, and with high velocities with a straight-line motion. In connection with this subject it may be mentioned that the Royal Meteorological Society have appointed a Wind-Force Committee to consider the relation existing between velocity and pressure, together with other anemometrical questions, and a preliminary report was read in the spring of this year.

THE publications of the Swedish Meteorological Office are somewhat in arrear, the volume recently published being for the year 1882. It contains observations *in extenso* from eighteen stations of the second order, and monthly and yearly results of 117 stations, among which are seventy-nine for temperature only and several that have been established in the interest of forestry. The Central Office has no station of the first order, but publishes the observations of the Upsala Observatory, which is an independent institution. From this Observatory we have very complete observations from 1855 to 1886, in addition to very valuable works on the classification of clouds and the movements of cirrus clouds, by Dr. Hildebrandsson. The Central Office publishes, however, a monthly weather report, in the service of agriculture, which is brought out to date. The Swedish network of stations was established in 1856, by the Royal Academy of Sciences of Stockholm, and in 1873 the present Office was founded, with Dr. R. Rubenson as Director. The Office for Marine Meteorology, established in 1877, is also an independent institution; the logs used are those of the English Meteorological Office, with the addition of the headings in Swedish. By mutual agreement, Sweden deals specially with the Baltic, while Norway takes the North Sea, the data collected being exchanged by the respective countries.

THE Report of the Meteorological Service of the Dominion of Canada for the year 1884, just issued by Mr. Carpmael, shows satisfactory progress in the various departments. Several new stations have been added, and the number for which monthly and yearly averages are given amounts to 136. Eighty-three per cent. of the storm warnings issued during the year have been verified; weather predictions have also been disseminated throughout portions of the country by means of large disks attached to the railway cars. These disks have the image of the sun, representing fine weather, the crescent moon, for showery weather, and a star, for wet weather, painted on them, in addition to words. The percentage of verification of these predictions is also very satisfactory. The climatological tables show that the highest mean annual temperature was 47°·81 at Windsor (Ontario), and the lowest at Fort Chipewan (North-West Territory), 26°·65. The records for Hudson's Bay Territory are not complete, but would probably have shown a lower mean. The maximum shade temperature was 100° at Chaplin (North-West Territory) in June, and the lowest at St. Andrews (Manitoba), – 53°·3, in January; with one slight exception this station had also the largest mean daily range, viz. 24°·75. Sunshine-recorders are erected in five provinces only; in these Winnipeg has the maximum sunshine, 45 per cent., and Pembroke (Ontario) the least, 30 per cent., of the possible amount. The greatest mean rainfall in any whole province was 48·46 inches in Newfoundland, and the least, 9·90 inches, in North-West Territory on 48·6 days. The greatest average of rainy days was 151·5 in Prince Edward's Island. The distribution of rainfall in Ontario is also represented by maps for each quarter and for the year. With a view to enhancing the value of the tables, we suggest the desirability of arranging them according to the international scheme, instead of in the present form; or at least of printing the extreme values in thick type, as is usually done in other countries.

THE chief feature of the United States *Monthly Weather Review* for July last is the unusually high mean temperature over the central and northern parts of the country; in some portions it averaged from 4° to 7° above the normal values, and was the warmest that has occurred since the establishment of the Signal Service stations. This fact is interesting in connection with the weather experienced in some parts of this country, where there was an excess of 2° to 5° in all districts. Descriptions of the storms which occurred over the North Atlantic are given; the average number of areas of low pressure for July during the last fourteen years is nine, for July 1887 the paths of seven such areas are traced, being two less than the average. The storm of the 26th is the one in which the high wave struck the s.s. *Umbria* (see NATURE, vol. xxxvi. p. 508). This depression was first charted in N. 55°, W. 25°, on the 25th, and its presence was indicated northwards of the British Isles during the 27th and 28th. The *Review* also contains a discussion of the North Atlantic storms during 1885; of sixty storms which advanced over the ocean from the American continent, twenty-eight were traced to European waters. Fifty-nine storms first appeared over the ocean, of which about 65 per cent. were traced to the west coast of Europe. A table is given showing the positions of centres of areas of mean high and low barometer for each month, and explains why in March and October the storm areas moved northward before reaching European waters, and that in August the depressions did not move eastward owing to unusually high pressure along the middle latitudes. Attention is drawn to the fact that, as a rule, the storms which do traverse the ocean leave the coast north of the fortieth parallel; only a very small number of the storms which advance from southern latitudes cross to the northward of the trans-Atlantic ship routes.

A SERIES of very interesting articles, from the pen of Dr. Oscar Doering, on the inter-diurnal variability of temperature at places in the Argentine Republic and South America generally, are being published in the *Boletin de la Academia Nacional de Ciencias* of Córdoba. Investigations of this kind have been very seldom undertaken, although Dr. Hann and Dr. Supan have pointed out that the variability of temperature is a factor of eminent importance, affecting the habits and character of mankind, and also partially the distribution of plants. Dr. Hann, in his elaborate paper upon this subject presented to the Vienna Academy on April 15, 1875, and based upon such observations as were then available, defines the variability of temperature as the differences of temperature of two immediately succeeding intervals of time which do not belong to the daily and yearly

period; or, in other words, as the differences of temperature between two short intervals that lie within the daily or yearly period, *minus* the amount of the periodical (or normal) variation. In part 4, vol. ix., of the above-mentioned Bulletin, Dr. Doering has calculated the variability for Concordia (lat. 31° 25′ S., long. 58° 4′ W.), but for three years only. The month of October has the maximum value, 4°·6, and April the minimum, 2°·8. The variability during spring is greatest, viz. 3°·9, and least during autumn, viz. 3°·0, and the mean for the year is 3°·6, or about 0°·4 above that for Buenos Ayres. The hourly observations published by the Meteorological Council, with the daily means ready calculated, afford excellent materials for similar investigations. The preceding number of the Bulletin contains the meteorological observations made at Córdoba during the year 1885. The absolute maximum shade temperature was 100°·9 in December, and the minimum 14°·9 in June, giving an annual range of 86°·0. The maximum solar temperature was 147°·4, in February. The mean relative humidity ranged between 81·7 per cent. in March and 61·1 per cent. in August. The rainfall amounted to 24·26 inches; the wettest month was March, 5·96 inches, and the driest, May, 0·04 inch. Rain fell on 71 days, and snow on one day. The times of rain at the moment of observation, an element much recommended by Dr. Köppen, are also quoted.

THE WORK OF THE INTERNATIONAL CONGRESS OF GEOLOGISTS.[1]

II.

MY only remaining subject is the representation of terranes on maps by means of colours. At present no two organizations and scarcely two individuals use colours in the same way; and it is probably true that every organization and individual publishing many geologic maps has at different times employed the same colour for different terranes, and different colours for the same terrane. It results that the map user can gain no information from the distribution of colours until he has studied the legend; before he can read a new atlas he must learn a new alphabet. The advantage to be gained by substituting a universal language for this confusion of tongues is manifest and great, and has justified the application of much time and attention by the Congress and its Committees. By a series of resolutions a partial scheme has been selected, one colour at a time, and the completion of the plan has been left to the Committee on the Map of Europe. That Committee has prepared a colour legend which is accessible to American geologists in the volume of information published by the American Committee. It is understood in a general way that the Congress reserves final action, and the published legend not only belongs specifically to the map of Europe, but is provisional; still, as this map, if generally approved, will unquestionably be declared by the Congress an authoritative pattern for the guidance of map makers, the plan should be freely criticized at its present stage. The selection of uniform colours is a far more delicate and important matter than the arrangement of taxonomic terms; for while ill-chosen words may quickly fit themselves to new uses, the adoption of an ill-arranged colour scheme must entail continual loss.

In my judgment the scheme provisionally chosen is defective in several particulars, to which I shall presently call attention; but it is necessary to introduce the discussion by a statement of the conditions to be satisfied by a standard colour scheme and a statement of the practical means available. The following are the principal conditions, arranged in an order embodying my estimate of their relative importance:—

(1) The map must be clearly and easily legible. Each colour must be so distinct from each other colour that it can be identified, whatever its surroundings; and all other conventions must be readily discriminated.

(2) The cartographic scheme must be adjustable to the geologic facts; it must not require that the facts be adjusted to it.

(3) The same scheme should serve both for general maps—as, for example, those representing only systems—and for detail maps, representing numerous smaller divisions.

(4) Undue expense should be avoided. The amount and consequent utility of colour cartography is largely limited by its cost.

(5) It should be easily fixed and retained in the mind. This is best accomplished by making it orderly.

(6) Other considerations permitting, the map should please the eye. Since the arrangement of colour areas cannot be foretold, this can only be accomplished by admitting a certain range of choice. If allowed sufficient latitude in the selection of tones, an expert colourist can ameliorate an offensive combination of hues.

(7) Other considerations permitting, the establishment of a universal system should involve the least possible inconvenience. But as the inconvenience of change is temporary, while the inconvenience of a bad system is lasting, this consideration should yield to every other.

The art of mapping geologic terranes by means of colour is well developed, and its methods, viewed from the geologist's stand-point, admit of easy characterization. Colour may be varied in two distinct ways—in hue and in tone. Hues differ in quality, as yellowish-green and bluish-green. Tones differ in strength, as pale green and dark green. A colour is printed either solid or broken; it is said to be broken when applied in a pattern, as in lines or dots, or when it is interrupted by a pattern. The difference between solid and broken colours is a difference of texture. The primary discriminations in mapping are through hue, tone, and texture.

The map engraver produces texture in three ways. In the first way a single impression is made with the broken colour. The white of the paper, displayed where the colour is interrupted, combines with the colour in the general effect, producing a paler tone of the same hue. In the second way two impressions are made, one with solid colour, the other with broken, and the two impressions have the same hue; they may or may not differ in tone. This is monochromatic over-printing, and its general effect agrees in hue with the single impression, but differs in tone, being darker. In the third way two impressions are made, one solid, one broken, and their colours differ in hue. This is bichromatic over-printing, and its general effect differs in hue as well as tone from each of the colours combined in it. The first and second ways produce texture monochromatically, and do not yield a new hue; the third way produces texture bichromatically, and yields a new hue. It is practically impossible to obtain a texture effect without modifying the original tone.

The natural gradation from hue to hue is absolutely continuous, and the number of hues is infinite; the number of tones of each hue is likewise infinite. The number of hues and tones the eye can discriminate is finite, but very great; it is stated that 1000 hues have been distinguished in the solar spectrum. But the number of hues and tones that can be combined in a map is small. As a matter of perception, every colour is modified by the colours adjacent to it. The same hue affords different sensations when differently surrounded, and different hues may afford the same sensation. The same is true of tones; and there is a certain interdependence of hues and tones in this respect. In a geologic map each colour is liable to fall into various combinations, and two colours little differentiated occasion confusion. There is therefore a somewhat narrow limit to the employment of hues and tones. The matter has not been fully worked out, but it is probable that twenty is as large a number of hues as can safely be employed in connection with tones. Texture admits of very great variation. The various colour schemes submitted to the Congress and printed in the report of the Bologna meeting afford, with their manifest permutations, about 200 distinct textures, and I am satisfied from a study of these and others that as many as 100 can be chosen that are not subject to confusion. It follows that a map or atlas expressing few distinctions need use only hues, or only hues and tones, but where numerous distinctions are to be made, recourse must be had to textures.

The printing of a large number of textures of the same hue produces a greater number of tones than can be discriminated, and its effect is to confuse and nullify any distinctions (within the range of that hue) based purely on tone. The printing of a large number of bichromatic textures causes the same result, and it also produces a greater number of hues than can be discriminated. Its effect is to confuse and nullify distinctions based purely on tone, or on hue, or on tone and hue together.

In the colour scheme prepared for the map of Europe, thirty-eight distinctions are made. There are twenty-four hues, and

[1] Vice-Presidential Address read to Section E of the American Association for the Advancement of Science, August 10, 1887, by Mr. G. K. Gilbert. Continued from p. 22.

the remaining fourteen distinctions are accomplished by variations of tone. While it may be possible to select twenty-four hues available for indiscriminate combination, there can be no question that those provisionally printed by the Committee will fail to maintain their distinctness when variously combined upon a map. Under the influence of such chromatic environments as are sure to be encountered, the four yellow hues of the Tertiary cannot be discriminated, and the same difficulty will arise with the two hues of gray assigned to the Carboniferous, and with the hues of gray and brown assigned respectively to the Permian and the Devonian. Some of the tones likewise are not sufficiently distinguished. Two of the blues of the Jurassic, two of the browns of the Devonian, two of the rose tones of the Archæan, and the two violets of the Trias, are open to this criticism. A certain amount of adjustment can be made in the final selection of inks, and probably all the defects from tone can be thus remedied, but the confusion of hues is more difficult to eliminate, for the great number of the hues interferes with the separation of those that are too approximate. To strengthen one contrast is to weaken another.

In order to judge of the availability of the scheme for the production of detail maps, it is necessary to consider the resolutions of the Congress as well as the printed legend. A resolution provides that the subdivisions of a system shall be represented by shades of the colour adopted for the system, or by broken colour or other texture devices; and it is further provided that the shades, whether produced by solid colour or by texture, shall be so arranged that the darkest or strongest represent the lower divisions of the system. The resolution is in French, and the word I have translated shade (*nuance*) is one which applies popularly to either hue or tone, while in the scientific terminology of chromatics it applies to hue only. The Committee on the map has taken it in its popular sense, and has represented some subdivisions by hues, and others by tones; for example, Pliocene and Miocene are assigned two tones of the same hue, while Oligocene and Eocene have each a separate hue. The Upper Cretaceous and part of the Lower Cretaceous are assigned a green hue in two tones, while the Gault and the Wealden, classed as subdivisions of the Lower Cretaceous, have independent hues of green. Of the six reds assigned to volcanic rocks, two agree in hue and differ in tone, while the remainder have distinct hues. As the legend stands, both major and minor distinctions—that is to say, the discrimination of groups, the discrimination of systems, and the discrimination of divisions smaller than systems—are all accomplished by differences of hue; while the discrimination of minor divisions is accomplished indifferently by variation of hue and by variation of tone. The same means performs several functions, and the same function is performed by several means.

It is stating the same thing from another point of view to say that the Congress and its Committees have used the term colour in its popular rather than its scientific sense. Scientifically, a colour is a particular tone of a particular hue, and the number of colours is infinite. Popularly, a colour is an assemblage of contiguous hues and their tones, to which a name has been given. Each hue and tone within the range covered by the name is a shade of the colour. It is in this popular sense that the resolutions assign a colour to each system, and assign shades of the system-colour to the subdivisions of the system.

Now, if in the variation of a system-colour, by textures or otherwise, a single hue is adhered to, the system-colour remains distinct from other system-colours throughout all its modifications and their modifications; but if hues as well as tones are varied, the inevitable result is confusion, for some of the hues of one system-colour will approach too near to hues of other system-colours. With a multiplicity of minor distinctions the main distinction of system from system will be lost.

Another difficulty lies in the fact that the Quaternary and Devonian colours, while strongly contrasted in tone, are nearly identical in hue. This does not affect their use in a general map, but in a detail map the stronger tones of the Quaternary gray will approach too closely the paler tones of the Devonian brown.

These criticisms apply to those features of the scheme which affect its adoption for general and detail maps of European countries. There is one of equal or greater importance affecting its application in other continents. It is adjusted to the rock systems of Europe exclusively, and makes no provision whatever for the systems of other parts of the earth. The geologists of Wisconsin, for example, cannot use it without calling the Keweenawan either Cambrian or Archæan. If they were in doubt which division should hold it, but inclined a little one way or the other, they could express their qualified opinion in the notation provided by the Map Committee; but having attained an unqualified opinion that the terrane belongs to neither of these two categories, they find no means for expressing their conclusions. The scheme cannot be applied to the geology of India, of New Zealand, or of Australia, without misrepresentation. It is not universal but local, and this because it is founded on the fallacy of a world-wide unity of geologic systems.

So far as the geology of the world is concerned, it would be better to adopt no convention at all as regards map colours than to adopt one carrying with it and promulgating a vicious classification. Uniformity is not worth purchasing at the price of falsification. If the members of the Congress cannot agree upon a plan having the flexibility demanded by the geologic facts, it will be best to limit its action to the local problems involved in the map of Europe. I believe, however, that the necessary flexibility is attainable; and before proceeding to further criticism of the Committee's scheme, I will give the outlines of a plan which appears to me to combine the advantage of flexibility with a number of other desirable qualities.

The plan is founded on the universality of geologic time and the diversity of local geologic histories as expressed in rock systems. Geologic periods are arranged in linear order. Each one adjoins the next, and together they constitute continuous geologic time, which we may conceive as represented by a straight line. The stratigraphic systems of a country have likewise an order of succession, and their arrangement is linear. They are not always continuous one with another, but the history recorded by the systems and the breaks between them is continuous, and may be represented by a straight line, equal and parallel to that of geologic time. And so for each country. A colour scale which shall represent each and all of these parallel lines must be itself linear and continuous, and fortunately we have such a scale furnished us in the prismatic spectrum.

I propose, first, that the continuous prismatic spectrum be adopted as the standard universal scale for continuous geologic time. I propose, second, that the conventional time scale, based on the geologic history of Europe, be complemented by a colour scale, prismatic but discontinuous. I would assign to each period, not a certain portion or area of the spectrum, but a specific colour defined by its position in the spectrum. This colour scale will also apply to the geology of Europe. I propose, third, that the students of each geologic district shall assign to the stratigraphic systems of that district a set of prismatic colours so selected from the spectrum as to properly represent the relation of each system to the time scale, provided that relation is approximately known. Under this rule a system corresponding partly with the Cretaceous and partly with the Jurassic will receive a prismatic colour intermediate between those assigned to the Cretaceal and Jural divisions of the time scale. I propose, fourth, that systems whose relations to the standard time scale are not even approximately known be given tentative positions in the time scale and assigned the corresponding colours; and that such provisional colours be distinguished by a special device.

Of this device I will speak later, but before we leave this part of the subject the capability of the plan to express the facts should be more clearly characterized. Continuous geologic time being equated with the continuous spectral band of light, each period is theoretically equated with a segment of that band including all the hues between certain limits. But practically the period is represented in the colour scale only by the central hue of the segment, and there is nothing in the nature of this hue to indicate the length of the segment. Similarly each local system is represented only by the hue corresponding to the middle of the equivalent period, considered as a part of the continuous time scale, and this hue gives no information as to the magnitude of the system or the duration of the corresponding period. When a non-European system is represented on a map with the Devonal colour, all that is expressed is that the middle of its period coincides with the middle of the Devonal period; the whole period may equal the Devonal or may be shorter or may be longer. With this limitation the scheme is able to express the exact facts, or the exact state of opinion, in regard to correlation.

I propose, fifth, that the subdivisions of systems be represented, if their number is small, by distinct tones of the hue assigned to the system, and if their number is great, by monochromatic textures. It having been provided that systems shall be distinguished by means of hues, it is now provided that hues

shall have no other function. This secures the integrity of the distinction between systems, whatever the minuteness of subdivision.

The idea of using the spectral colours in their proper order is not novel. It has entered into half the plans submitted to the Congress, but each author has introduced other colours also, or else has undertaken to use the spectrum colours more than once, under the impression that they do not afford the necessary range or variety. This impression is based largely upon the popular meaning of the word colour. It is indeed true that if we limit ourselves to those parts of the spectral series which have univocal names, we have only six or seven distinctions; and it is further true that if we have recourse to binomial designations, such as yellowish green and greenish yellow, we obtain rather indefinite conceptions; but to men of science there are better resources than those afforded by the language of every-day life. The spectrum has been elaborately studied, and the relations of its dark lines to its colours have been determined. Its wave-lengths have, moreover, been measured, and by such means as these we are furnished with three different scales, any one of which is adequate to the precise definition of any hue of the continuous series. What needs to be done is this. When the divisions of the time scale have been decided on, the spectrum must be studied to ascertain the best selection of hues. Their number must, of course, be that of the number of divisions of the time scale, and they must be so chosen that the degree of separateness of adjacent colours shall be everywhere the same, as judged by the normal human eye. Then define each hue by its wave-length or its position in the Kirchhoff scale, and define it also in terms of the best combination of pigments with which it can approximately be reproduced for practical use. It is, of course, impossible to copy the prismatic colours with accuracy, because the colours of pigments are impure, but this difficulty will not seriously interfere with the employment of the prismatic colours as a standard.

The practical question whether the spectrum will give a sufficient number of hues so far separated from each other as to be distinguishable in all the arrangements occurring on maps has received such consideration as I have been able to give it, and it is my judgment that the maximum number of hues that can safely be used falls somewhere between fifteen and twenty. There will certainly be no difficulty in thus constructing a standard colour scale with about a dozen terms.

The employment of the spectral colours in this manner leaves three groups of colours unassigned—the purples, the browns, and the grays. If the spectral colours be arranged on the circumference of a circle so that each diameter of the circle connects hues that are complementary, it is found that they occupy the greater part, but not quite all, of the circumference, and the colour needed to fill the vacant arc is purple. The hues of purple might then, if deemed necessary, be added to one end or the other of the spectrum, thus increasing the range from which to select colours for the time scale.

My sixth proposition is to assign the browns to volcanic rocks. I would leave the grays unassigned.

It will be observed that no intimation has been given as to whether the violet end of the spectrum should apply to the newest system of strata or the oldest. It must of course be definitely assigned to one or the other, but the particular assignment is a matter of indifference.

The main features of the proposed prismatic scheme have now been set forth, and you are fairly entitled to exemption from the minor features, but there is one detail that can hardly be omitted. In one of the main propositions it was provided that some special device should distinguish colours assigned to uncorrelated systems, and I feel it incumbent to show that a suitable device can be found. Of a number that have occurred to me as about equally available, I will mention but a single one—the over-printing, in small dots, widely separated, of the complementary colour. The complementary colour is selected because it does not disturb the relation of the system-colour to the colours of adjacent systems. Bichromatic over-printing produces a hue intermediate between the two hues combined, but the hue mid-way between a system-colour and its complementary colour is white or gray, and if only a small amount of the complementary colour is added, the system-colour merely becomes paler or duller, when viewed from such a distance that the colours blend.

The prismatic colour scheme, having been constructed for the express purpose of securing a degree of flexibility that will fit it for universal use, need not be further compared in that regard with the scheme published by the European Map Committee. Enough has also been said to show that its superior perspicuity is claimed both for general and for detail maps. A few words will suffice to compare the two systems in other respects.

As regards the expense incurred in the production of general maps, neither has any notable advantage, and they are not yet sufficiently developed to permit a comparison as regards the cost of detail maps. Their capability for the production of pleasant colour effects can best be judged when maps have been actually made, but it may be said in a general way that the Committee's scheme will afford more strong contrasts between adjacent colour areas than the prismatic. The maps coloured by the former will be relatively lively, those coloured by the latter relatively quiet. It is provided by the Committee that the volcanic colours shall be not merely red but strong. On a general map volcanic areas cover comparatively small spaces, and strong reds thus disposed will ordinarily add brilliancy; but the detail map of a volcanic district, thus coloured, will be disquietingly suggestive of active eruption.

The alphabet of colours for the prismatic scale will be the more easily learned of the two, because it is orderly, and because its order is already familiar in the spectrum. The Committee's scheme, however, has some old-fashioned mnemonic features which the prismatic lacks. The green of the Cretaceous is connected with greensand, the red of volcanic rocks with fire, and the rose of the Archæan with feldspar; and the gray of the Carboniferous mildly suggests the blackness of coal.

In respect to facility of introduction the Committee's scheme, being essentially a compromise of existing colour scales, has the advantage that to most users it is not entirely novel. The prismatic scheme on the other hand has the advantage of being orderly. It scientifically differentiates the functions of hues and tones, and though each one of its colours may be different from what the individual geologist has previously employed for the indication of the same system, the order of the colours is already familiar to him in another way.

This closes my review of the various works undertaken by the Congress. Some of these have been favoured, others opposed, and reasons have been given. But there is a general consideration or criterion applicable to all, which has nearly escaped mention, although it is of pre-eminent importance. When a matter is proposed for regulation by the Congress, the first question which should be asked is whether it falls within the legitimate purview of a convention of geologists. It manifestly does not if it belongs to some other science rather than to geology, and objection has on this ground been made against the regulation by our Geologic Congress of the nomenclatures of palæontology and mineralogy. But not all geologic matters even are properly subject to settlement by convention. This is peculiarly the case with geologic facts. Science is distinguished from the earlier philosophies of mankind by the peculiarity that it establishes its fundamental data by observation. The old philosophies were founded largely upon assumptions, and it was not deemed illogical—perhaps it was not illogical—to appeal to the authority of an assemblage of experts for the establishment of fundamental assumptions. But for science it is not merely illogical, it is suicidal, to establish facts in any other way than by observation. No vote of the most august scientific body can possibly establish a fact, and no vote can have any weight against a good observation.

Now the entire science of geology, using the phrase in a strict sense, is constituted by the aggregation and arrangement of facts, and none of its results can be rendered more true or be more firmly established, or be prevented from yielding to contradictory facts, by conventional agreement. A classification, if it has any value whatever, is merely a generalized expression of the facts of observation, and is outside the domain of the voter. If it comprises all the essential facts, its sufficiency will eventually be recognized, whether its authority is individual or collective. If it does not comprise them, it will inevitably be superseded, by whatever authority it may have been instituted. For this reason I am opposed to the classification by the Congress of the sedimentary formations, and likewise to the classification of volcanic rocks, and I also regard it as ill-advised that the Congress undertook the preparation of a map of Europe, for that—if more than a work of compilation—is a work of classification.

If we examine the other undertakings of the Congress—the definition and gradation of taxonomic terms, the systematization of terminations, the selection of a scale of colours for geologic maps, and the selection of other conventional signs for the

graphic expression of geologic phenomena—we find that they all belong to the means of intercommunication of geologists. They affect only the verbal and graphic technical language of the science. Of the same nature is the arbitrary time scale whose preparation I favour—a conventional terminology for the facts of correlation. So we may say, in general, that the proper function of the Congress is the establishment of common means of expressing the facts of geology. It should not meddle with the facts themselves. It may regulate the art of the geologist, but it must not attempt to regulate his science. Its proper field of work lies in the determination of questions of technology; it is a trespasser if it undertakes the determination of questions of science. It may decree terms, but it must not decree opinions.

TECHNICAL EDUCATION.[1]

THE present century has witnessed a vast and almost incredible change in the great industries of the world, and in the progress of the arts and manufactures. The causes of this great change are various, though mutually dependent upon each other, such as the cessation of the great wars that had for so long ravaged the continent of Europe, which enabled many of the most vigorous minds to be turned to the arts of peace; the rapid growth of population, which rendered the wants of mankind more pressingly felt; and the more general spread of education, which caused the great discoveries that have enriched this period to be eagerly taken advantage of and adopted.

Among the many results which have ensued, is one which must be carefully studied, affecting as it does in a peculiar degree our own country at this time.

Since the latter half of the last century, when by the disappearance of forests in the iron-producing districts, resulting from the use of timber as fuel, maternal Necessity had brought forth an invention in the shape of the process of smelting iron ore with coal, progress in machinery and manufactures had steadily been made. The great natural advantages arising from the conjunction, not only of coal and iron in the same locality, but also their immediate proximity to the limestone required in iron-smelting operations, had greatly contributed to this advance, until this country, instead of importing four-fifths of the whole iron used from Sweden, as was the case in 1750, had become the greatest iron-producing country of the world. The invention of the steam-engine in conjunction with the power-loom and other important machines, greatly contributed to the growth of the factory system, the establishment of the cotton, linen, and woollen industries, and the rapid increase of manufactories in general. Owing to the insular position of Great Britain, and the prohibitive laws in force, until fifty years ago the nature of the machinery used in all these manufactures, as well as the technical knowledge and skill of the workman, was prevented from being carried abroad. Thus, as stated in the recent Report of the Commissioners on Technical Education:—

"When, less than half a century ago, Continental countries began to construct railways, and to erect modern mills and mechanical workshops, they found themselves face to face with a full-grown industrial organization in this country, which was almost a sealed book to those who could not obtain access to our factories."

This artificial state of things was not destined to last, for, on the one hand, these countries were keenly alive to the importance of possessing such manufactures, and were determined to obtain them at all costs; and, on the other, it was greatly to the immediate advantage of our manufacturers to sell freely in such a market as began to be opened to them. At the same time skilled artisans were easily found who were willing to accompany abroad machinery which had been constructed in this country, and thus to become the means of disseminating technical education of the most practical type amongst those who were quite as industrious and frequently better educated than the workmen at home.

The efforts of foreign nations to establish mills and workshops of their own did not cease here; for, recognizing the necessity of specially spreading technical knowledge by all possible means, technical schools, instituted and supported by the State, at which instruction could be obtained free, or at almost nominal cost, were established in numerous places all over the Continent. The larger number of these schools have been institutions at which the scientific principles underlying industrial and manufacturing operations, rather than the actual operations themselves, were taught, although there are also in lesser number special technical schools, such as the weaving schools of Chemnitz in Saxony, of Crefeld in Rhenish Prussia, of Basle in Switzerland. From these various schools, numbers of highly educated men have been sent out year by year, prepared, when becoming foremen, managers, or employers of labour, to take advantage of the latest discoveries and improvements in various branches of industry, and keenly alive to the fact that "knowledge is power."

Notwithstanding all this, an enormous increase of trade and prosperity was enjoyed by this country for many years, and notably was this the case after the first International Exhibition in Hyde Park, in 1851, which Exhibition revealed to visitors from all parts of the world much (some persons of the old school are to be found, who assert *too* much), concerning the perfection of our machinery and processes of manufacture which had been scarcely realized before, even by ourselves. This prosperity apparently reached a climax from ten to fifteen years ago, and, since then, trade has assumed a very different aspect. At first the change was felt in relation to countries whose resources were in some respects comparable with our own, and afterwards with others less favourably situated, and in place of supplying them with manufactured articles and machinery, they began to enter into competition, and in many cases successful competition, with this country, even in markets hitherto considered all our own. Indeed, a positive reflex action has actually occurred in some important branches of industry and foreign iron, machines, hardware, and textile goods are imported for home use. The result of this competition has been keenly felt, and the consequent struggle which has taken place in these times of peace has been, and now is, almost as determined and often as bitter as in an open war. That rather doubtful compliment once paid by a great general to the British soldier, that he never knew when he was beaten, could scarcely be applied to the British manufacturer, since there is a very speedy way of settling this point in a commercial transaction; but the question upon which knowledge has often been wanting and information sometimes too tardily sought, is rather as to the cause and its remedy. In some cases the cause is obviously due to the lower wages and longer hours for which foreign workmen will toil, and it may be mentioned, as pointing to what may be sometimes possible in this case, that in the neighbouring industry of wire-drawing at Warrington, which was threatened with extinction, the German competition was entirely met and overcome by the wire-workers voluntarily accepting a reduction in wages of 10 per cent., after four of their delegates had visited the Black Forest and ascertained for themselves full particulars as to the wire industry of that district.

But, on the other hand, there are branches of manufacture in which the state of foreign workmen and workwomen is so pitiable that no right-thinking person would desire to have increased trade in this country at such a price to our own people, though happily there is not much fear of this, since the movement is rather in the other direction. But the question of wages is only one of many causes, for it has been asserted by excellent authorities that it is not in those branches of industry in which foreign wages are lowest and hours longest that competition presses most heavily upon us. Thus, according to the recently published Consular Reports, we have still something to learn in several directions in the matter of finding out fresh markets and accommodating our productions to native wants, instead of trying to force goods of our own pattern and design where they are either not in accordance with native views and prejudices, or are unsuitable to the locality. Again, it is not only the Germans who stamp the words "best Sheffield steel" upon cast-iron axes and knife-blades: neither in the matter of shoddy-manufacturers can this country afford to throw stones at our foreign rivals.

It is not, however, the object of this address to enter into a discussion of the various causes of trade depression, and still less to presume to say how such an undesirable state of things may be met and overcome, but to consider a subject which has recently been very vigorously brought forward in connexion with this matter under the title of "Technical Education." No branch of education has of late attracted so much attention as this. It has formed not only the text of the Presidential Address of the British Association in 1885, and part of that at the recent

[1] Part of Inaugural Address of session of University College delivered at St. George's Hall, Liverpool, on October 1, 1887, by Prof. Hele Shaw, M.Inst.C.E., of the University College, Liverpool.

address at Manchester, but of innumerable other speeches, pamphlets, papers, and even books, one of the very earliest and most brilliant of which was a treatise from the pen of the late Mr. Scott Russell. It has been quite recently the subject of a special Government Bill, which was considered sufficiently urgent to be carried through almost to the last stage when other Bills were being dropped right and left, and then disappeared only with the full assurance of a revival in more vigorous form at an early period of next session; while only in last July there was formed "A National Association for the Promotion of Technical Education," which numbers as its President, Vice-Presidents, and Committee, many of the most able politicians, experienced men of business, and well-known men of science.

These facts are quite sufficient to show that there is now a very prevalent and wide-spread belief that the subject of technical education has become one of pressing national importance. There are, indeed, already not wanting persons who connect the subject with the terms "foreign competition" and "commercial depression," by a train of reasoning apparently somewhat as simple as the following:—

1st proposition.—Bad trade is the result of foreign competition.

2nd proposition.—Foreign competition derives its strength from superior foreign technical education.

Conclusion.—Therefore bad trade at home is due to superior technical education abroad.

This mode of reasoning is brief and conclusive enough to satisfy even the most superficial, it is easily portable, and has the advantage of admitting of illustration in certain special cases in which both propositions and conclusion are true, but it is nevertheless a striking example of the danger of arguing from the special to the general. Without, however, accepting such a sweeping generalization, it may be safely said that foreign countries have derived great benefit from their systematic encouraging of technical teaching, and we may proceed to consider briefly what progress we ourselves have made in this direction.

In the first place it may be well to ask what the term "technical education" really means? Most people have, no doubt, a general idea on the subject, but there are a great many who freely discuss the question, who would be woefully at a loss if asked for an exact definition; and if anyone doubts the truth of this, let him try the experiment on a few friends. The answer which will generally be given, with some hesitation, will probably have some not very distinct reference to instruction in the use of tools, backed by allusion to carpentering by way of illustration, or will, perhaps, be some mention of chemistry, or other branch of science, or, as a final resort, "something to meet the German competition." Now the fact is that the first of these may not be really technical instruction at all, but only manual training as part of a general education, as, for instance, is now given out of school hours in the working of wood to the boys at most of our Colleges, partly to keep them out of mischief and partly to train the hand and eye, but in which case there is not the slightest intention or idea that any of the boys shall actually become a carpenter. The last answer, however grotesque it may seem, is much nearer the truth, as it connects technical instruction with a special *object* in view. Now that this is really the idea of those who have thought most carefully over the subject is made clear by the terse and excellent statement of the aims of the Association for the Promotion of Technical Education, one of which is "to effect such reforms in our educational system as will develop in the best way the intelligence of those of all classes upon whom our industries depend," the Association itself being formed because of "the general expression of opinion throughout the country as to the necessity of a reform in our system of national education, with the object of giving it a more practical direction." Thus we may accept the following definition of a writer on the subject, that "by technical education is meant special instruction in some scientific, artistic, or mechanical process or handicraft as distinguished from purely literary instruction"; or that by another writer, who defines it as "special training for an industrial pursuit as distinguished from a general preparation for any calling hereafter to be chosen." Thus technical education will comprise a very wide range of subjects, not those merely taught with a view to manufacturing, mechanical, and artistic pursuits, but will comprise the instruction given in a medical school, in an agricultural college, and even commercial education, which last now forms a distinct feature of our own College, and the reform of which branch of education is one of the special objects of the Association above alluded to. It is therefore at first surprising to the uninitiated that we find the following definition in the recent Bill for Technical Education: "The expression technical instruction means instruction in the branches of science and art with respect to which grants are for the time being made by the Science and Art Department, or in any other subject which may for the time being be sanctioned by the Department." This definition is no doubt quite satisfactory to the authorities of the Department, although it savours strongly of the opinion attributed in a well-known series of rhymes to a certain eminent University don, who is made to assert—

> "I am the Master of this College,
> And what isn't taught here isn't knowledge."

And though this definition happens at present to exclude manual and workshop instruction, concerning which the mover of the Bill, Sir Wm. Hart Dyke, expatiated somewhat eloquently and at considerable length when moving the second reading of the Bill—but this is a trifling matter, as no doubt when the Science and Art Department has had time to go into the matter, and to study the subject, and has made arrangements for teaching and examining it, it will be "sanctioned" with the rest, and become technical instruction. It must, however, be recognized that the Science and Art Department is the most important institution in this country for the promotion and encouragement of technical education, and has done a work, especially in the direction of evening-class teaching to the artisan class, which must have proved of incalculable benefit, and it will be well to study the progress made in science instruction, as affording some index of our general progress in technical education. The following table gives the result of work during the last ten years, showing in three columns: (1) the amount of the grants given to teachers for successful candidates on the system of payment by examinational results; (2) the actual number of students under instruction in science classes fulfilling conditions which would enable a grant to be claimed; (3) the number of papers actually worked in different science subjects. The three columns are independent of each other in a certain sense, since a registered student may either take several papers, or may, on the other hand, possibly not come up for examination at all, or, coming up, may fail to secure a grant.

TABLE I.—*Results of Science and Art Department during the last Ten Years.*

Year.	Grants. (1)	Students under Instruction. (2)	Examination Papers actually Worked. (3)
	£		
1878	39,073	59,705	66,365
1879	41,036	56,752	70,248
1880	43,863	60,041	72,428
1881	47,231	61,180	75,735
1882	49,700	67,315	79,786
1883	50,967	71,164	83,387
1884	61,638	77,519	90,825
1885	69,113	81,491	101,275
1886	79,000	97,664	118,241
1887	88,000	103,362	131,896

The results are striking, but in order to reveal their significance more closely, the diagram, Fig. 1, is reproduced from a recent memorandum of expenditure and estimates of the Department, in which the height of the lines in each year from the base line gives the value of grant, number of students, or of worked paper.

The three curves represent at once to the eye the rapid progress which is being made. Indeed, the rate of increase is twice as great during the last two years as during previous years, and, so far from there being any want of appreciation of technical instruction, the results are such as might possibly cause the taxpayer some concern; on this point, however, the memorandum states:—"There is no reason to suppose that the expenditure will rise at the present rate; on the contrary, even without look-

ing at the increased rate of rise of the last few years, as a sudden augmentation due to special causes, it is obvious that as the limit is approached the rate of rise must rapidly diminish. This limit, as far as it can be arrived at by calculation from population, &c., probably about 200,000 persons under instruction in science—there were last session 110,000 under instruction. Continuing the curve for science as it may reasonably be expected to run, we should arrive at about 110,000 in 1896." In any case there is no real cause for alarm, because the standard of work required to secure a grant can always be raised, and, as a matter of fact, appears to be steadily rising year by year, and, after all, the sum of even £101,175, which is the estimated expenditure for the current year in aid of science instruction, is a remarkably small annual expense for the instruction of 103,362 students all over the country.

There has been for several years at work another central agency, which promotes technical instruction in the same manner as the Science and Art Department, viz. by payment upon the results of examination. This body is known as the City and Guilds Institute of London. These examinations carried on by this body were originally established in 1873 by the Society of Arts—the subject that year being cotton manufacture, steel, and carriage building, the number of candidates being respectively one, two, and three, making a grand total of six. The next year, gas manufacture and agriculture were added, and the total rose to thirty-six. Subjects continued to be added, and the

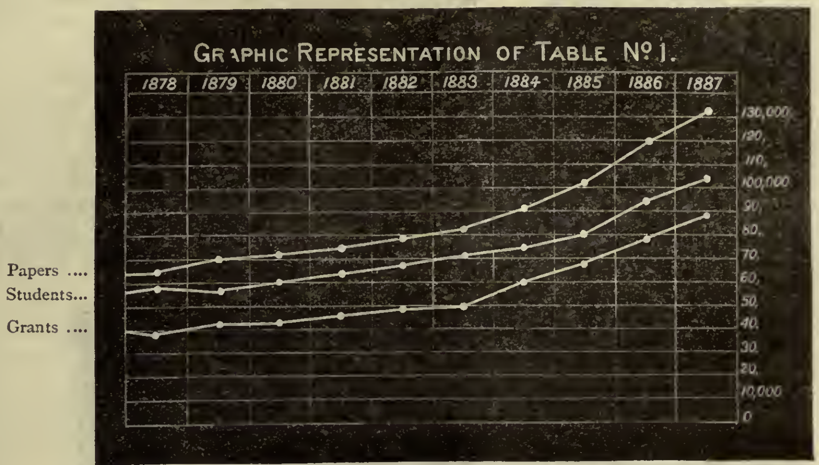

FIG. 1.—Science and Art Department.

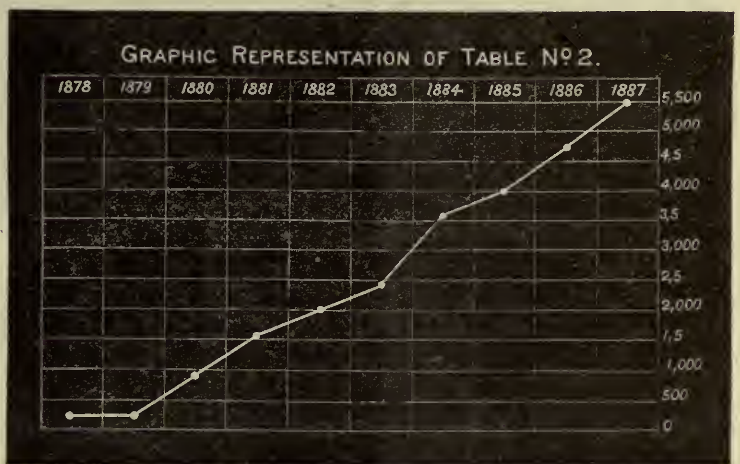

FIG. 2.—City and Guilds of London.

numbers to rise year by year, until ten years ago the latter had reached 184, since when the following table shows the progress made, the City and Guilds taking over the whole responsibility of the work in 1881.

TABLE II.—*Society of Arts and City and Guilds Examinations.*

Years.	1878	1879	1880	1881	1882	1883	1884	1885	1886	1887
Number of Candidates.	184	202	803	1563	1972	2397	3635	3968	4764	5508

I have plotted the above results in a similar manner to those of the Science and Art Department, and it will be seen (Fig. 2) that the rate of growth is far more rapid; and rich as are the worthy livery companies of grocers, fishmongers, tanners, spectacle makers, and others, who form the City and Guilds Institute, they too must have reason to confess that technical education, towards which they have recently contributed not less than a quarter of a million of money, is not quite at a standstill, for at the present rate of growth the number of candidates, large as it now is, will have doubled in the next seven years, though even this, with an assured income of £33,000 a year, may not give them cause for alarm. It may be well to explain that the examinational work of the City and Guilds, and that of the Science and Art Department, not only do not clash, but bear an important and valuable relation to each other. Thus the former is more distinctly technical, dealing with special details of trades

and manufactures, and the term "technological examination" is always employed to emphasize this point, and before a full technological certificate is granted by the City and Guilds Institute in any subject, certificates in the elementary stage of certain specified theoretical examinations of the Science and Art Department must be produced. A comparison of a few of the subjects will at once make this clear, the numbers appended to the subjects in the following list being those attached to them in the syllabus of each examining body.

SCIENCE AND ART DEPARTMENT.	CITY AND GUILDS.
Subject II.—Machine Construction and Drawing.	(27) Tools. (*a*) Wood Working. (*b*) Metal Working.
Subject III.—Building Construction.	(34) Carpentry and Joinery. (35) Brickwork and Masonry.
Subject VI.—Theoretical Mechanics. Subject VII.—Applied Mechanics.	(28) Mechanical Engineering.
Subject IX.—Magnetism and Electricity.	(22) Electrical Engineering. (*a*) Telegraphy. (*b*) Electric Lighting. (*c*) Electrical Instrument Making.
Subject X.—Inorganic Chemistry. Subject XI.—Organic Chemistry.	(1) Alkali and Allied Branches. (4) Coal Tar Products. (7) Oils, Varnishes. (8) Oils and Fats. (9) Gas Manufacture.
Subject XIX.—Metallurgy.	(10) Iron and Steel Manufacture.

Practical examinations are held by the City and Guilds in weaving and pattern designing, in metal plate work, in carpentry and joinery, and in mine surveying, while last year, for the first time, an examination was held in typography. This latter was conducted in several printing works placed at the disposal of the Institute, and thirty-two out of the seventy-seven candidates succeeded in composing and printing the difficult manuscript supplied to them—sufficiently well to obtain a certificate.

There is nothing at all approaching our own system of payment by results in any country in Europe, and eminent foreign educationalists have frequently deplored the absence of such in their own respective countries. This system has given particular vitality to that most valuable kind of education—evening class instruction; and as an examiner for both the bodies above alluded to, and after an experience—not a very enjoyable experience, and not the experience that a rich man would continue to indulge in—of upwards of 6000 examination papers, I may be permitted to testify to the valuable nature of the work done by the students, and the possibility of almost complete prevention of "cram" when proper precautions are taken. Thus, though large numbers of technical night classes exist all over the Continent, it is very doubtful if the results obtained by them are superior or even equal to our own.

When it is considered what splendid technical training the workshops and manufactories of this country have afforded, there will, perhaps, appear to be very good reasons why, originally, technical schools were not so extensively instituted at home as abroad, where almost all foreign States have established and maintained technical schools, the École Centrale at Paris being almost the solitary exception to this rule. When, however

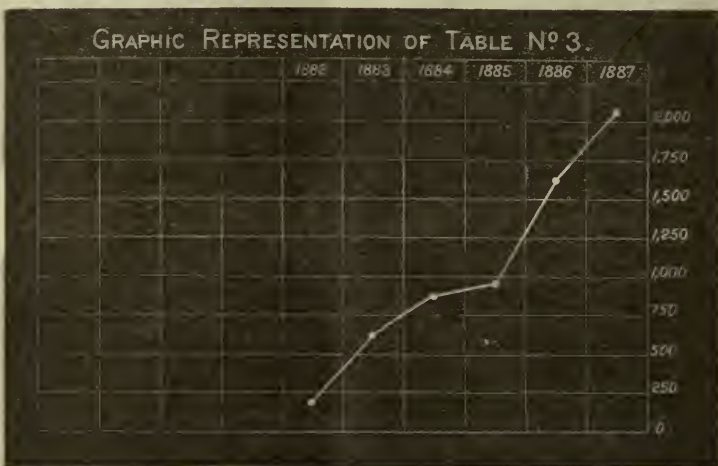

FIG. 3.—University College, Liverpool.

their need was felt, it was not left to the slowly-moving wheels of State to bring such schools on the scene. At first these schools took the form of lectureships and chairs in constructive science, for which the term "engineering" was conveniently adopted, the first of these being at London, Glasgow, and Manchester, and founded in connexion with the local Colleges. These have been gradually followed by Engineering Schools in the Colleges at Leeds, Sheffield, Nottingham, Dundee, Newcastle, Bristol, Birmingham, and last, but it is hoped not least, at Liverpool. These schools give instruction not merely in engineering subjects in a narrow sense of the word, but include in their courses of teaching the wide range of subjects necessary for laying a firm foundation for a successful career in any one of the constructive professions, and prepare a student to enter any of the particular branches into which engineering has become differentiated, and compare in this way with chemical teaching, which is given in places like this city—which may be specialized with a view to particular local industries. Besides these schools, others have arisen of a more special nature, due to liberal-minded men and public-spirited bodies, such as the Weaving and Dyeing Schools at Leeds, upon which the Worshipful Company of Clothworkers have spent between £20,000 and £30,000; the Technical Schools at Huddersfield, Bradford, Glasgow, Manchester, and other towns, some of which will bear comparison with the celebrated foreign schools of Chemnitz, Mulhouse, Verviers, Crefeld, and Vienna. The benefit of such schools has already been felt, for it is most encouraging to find amongst many similar opinions the testimony of the Technical Education Commissioners that—"In those textile manufactures in which other nations have hitherto excelled us, as in soft all-wool goods, we are gaining ground. We saw, at Bradford, merinos manufactured and finished in this country, which would bear comparison in texture and colour with the best of those of the French looms and dye-houses, and in the delicate fabrics of Nottingham and Macclesfield (thanks in great measure to their local Schools of Art) we no longer rely upon France for design."

The address, after pointing out that this country was, taken as a whole, after all not in such a deplorable state with regard to technical education, asserted that such education was of two kinds—general and special. General technical education may be said to be that necessary in all large centres of population, being the preparation for such callings as engineering, architecture, medical science, and other professions, which at any rate a certain percentage of the inhabitants will always follow, besides training of another kind suitable to the artisan class. Special technical education is that necessary in a locality where there are special industries, instances of which have already been given, and others will readily occur to the mind.

The remainder of the address was devoted to considering the educational work of Liverpool and its special technical require-

ments. A brief reference was made to the progress of University College, as shown by the following table of attendances in the day classes since its foundation in 1882.

TABLE III.—*Entries in Day Classes, University College.*

1882.	1883.	1884.	1885	1886.	1887.
189	625	883	944	1642	2063

These results are better shown graphically in Fig. 3.

During the last few months no less than £30,000 has been contributed to the Engineering Department alone, but the other professorships are all provided for upon an equally sound basis, and Prof. Hele Shaw thus concludes:—

"Hence, side by side with teaching, directed—sometimes perhaps only directed—to the practical purposes of life, we shall, thanks to the liberal endowment of chairs of language, of literature, and of art, always have the more liberal studies, and, as their exponents, scholars of the highest culture. Thus every individual professor thinking, as he ought to think, his subject to be the most important of all (a feeling I must, in common with the rest, confess to having myself), and so led to work for its due recognition, the happy mean will doubtless be maintained between mere idealism on the one hand, and mere routine on the other. Yet one word more. There is another motto prominent upon the College crest ('*Fiat lux*'), in the spirit of which work will always be true to the highest ideal. Our national life depends upon our national progress, and when we cease to advance, decay will speedily follow. Just as surely our College life, vigorous because growing, depends for its vitality upon the reality of the effort we make to carry forward the light of truth, and should never suffer because we strive to keep in touch with the requirements of practical life. Scientific investigation and philosophic research must have their proper place and support, and if allowed fair scope for development, will exercise the needful influence, and one that will be of untold value upon such narrowing tendencies as there may be in our various schemes of technical education."

SCIENTIFIC SERIALS.

American Journal of Science, October.—The relations between wind velocity and pressure, by H. Allen Hazen. A comparative study is made of the experiments carried out by Borda, Hagen, Piobert, Didion, Morin, and more recently at Washington, showing the great necessity there is for further research before absolutely trustworthy results can be obtained. Experiments are much needed, especially with larger plates than 2 feet square, with bodies of other forms than those hitherto employed and with high velocities by a straight-line motion.—Is there a Huronian Group? (continued), by R. D. Irving. After establishing the existence of a true Huronian Group, the author proceeds to define its character, showing that many formations even in the Lakes Superior and Huron regions, have been wrongly referred to this type. The presence is clearly demonstrated of two entirely distinct and mutually discordant series in the Marquette, Penokee, and Menominee districts. In all these regions there are great discordances between a lower set of gneisses and other crystalline schists, intruded by granite, and an upper set of detrital rocks carrying iron. The so-called Animiké series is then considered, and referred with the older Penokee formations to the Huronian system.—Oxygen in the sun; contributions from the Physical Laboratory of Harvard University, by John Trowbridge and C. C. Hutchins. The experiments here described have been carried out in order to test the soundness of the conclusion generally drawn from Dr. Henry Draper's discovery of bright spaces in the solar spectrum apparently coincident with the bright lines of the spectrum of oxygen. This conclusion is shown to be at least premature, and in the numerous photographs taken of the solar spectrum by them the authors have failed to discover any line that could with certainty be pronounced brighter than its neighbours. The bright bands of Dr. H. Draper's spectrum are found to be occupied by numerous dark lines of various degrees of intensity; but the hypothesis of Prof. J. C. Draper that these are the true representatives of the oxygen lines is rendered untenable by the lack of any systematic connection between the two.—Bismutosphærite from Willimantic and Portland, Connecticut, by H. L. Wells. An analysis of two specimens of basic bismuth carbonate shows them to be apparently identical with Weisbach's bismutosphærite, the composition of which had been considered somewhat doubtful.—Note on some remarkable crystals of pyroxene from Orange County, New York, by George H. Williams. The lower back part of some of these specimens is exactly like the lower front quarter, but in a reversed position, so that the lower half is a twin as represented by Von Rath, while the upper half is apparently simple and of the usual habit.—The flow of solids, or liquefaction by pressure, by William Hallock. The experiments here described point at the conclusion that pressure alone cannot truly liquefy a solid—that is, diminish its rigidity; consequently neither can chemical or mineralogical changes be produced by pressure alone without a rise of temperature.—Analysis of some natural borates and borosilicates, by J. Edward Whitfield. The series of analyses here described have been undertaken to verify, if possible, the given formulæ, and correct errors caused by defective analytical methods of estimating the boric acid of natural borates. The percentages of boric acid as here determined by direct analysis do not differ greatly from the results of Stromeyer's and Marignac's methods.—The Texas section of the American Cretaceous, by Robert T. Hill. In this paper the author studies the true character of the deep marine Cretaceous strata already determined by him in Texas, at the same time explaining some new features of it, which throw much light on the various American chalk systems.—Notice of new fossil mammals, by O. C. Marsh. Descriptions are given of some new species of *Bison alticornis*, *Aceratherium acutum*, *Brontops robustus*, *Menops varians*, *Titanops elatus*, and *Allops serotinus*, recently received at the Yale Museum from the West.

Rivista Scientifico-Industriale, September 15.—On the pressure of mixtures of gases and vapours, and on Dalton's law, by Prof. G. Guglielmo and V. Musina. Regnault, while admitting that Dalton's law on the tensions of vapours in gases is not strictly verified, and that the maximum tensions are less in gases than in vacuum, concluded that the law was theoretically exact, and would even be verified in practice in a receptacle whose walls were formed of the liquid generating the vapour. The experiments here described have been carried out for the purpose of testing the accuracy of this view, with the result that the attraction of the walls for the vapour is far from sufficing to explain the discrepancies of the Daltonian law. Consequently this law is not even theoretically correct, at least so far as can be concluded from these researches, which, however, will require to be repeated with apparatus insuring greater precision than those here employed.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 31.—M. Janssen in the chair.—Observations of the minor planets made with the great meridian of the Paris Observatory during the second quarter of the year 1887, by M. Mouchez. The right ascension and Polar distance, with correction of the ephemerides, are given for Belisane, Athor, Asterope, Nausicaa, Vesta, Antiope, Amphitrite, Polana, Bellona, Hecuba, and Arethusa.—On the Observatory of Nice, by M. Faye. In connection with the Geodetic Conference just concluded at Nice, the author announced that the magnificent Observatory of that place, due to the munificence of M. Bischoffsheim, is now completely finished. This institution, he added, is entirely at the service of the astronomers of all nations who may wish to avail themselves of its exceptional advantages in the prosecution of their researches.—New fluorescences with well-defined spectral rays, by M. Lecoq de Boisbaudran. The results are described of spectral researches made with gallina and samarine ($Ga_2O_3 + \frac{1}{50}Sm_2O_3$) moderately calcined; the same very highly calcined; gallina and the earth $Z\alpha_2O_3$; gallina and the earth $Z\beta_2O_3$; and alumina with a small portion of the oxide of praseodyme (Pr_2O_3) highly calcined.—Observations of the new planet, Peters (270), made at the Observatory of Algiers with the 0·50m. telescope, by MM. Rambaud and Sy. The observations cover the period from October 14 to October 17.—Observations of the new planet, Knorre (271), made at the same Observatory by the same astronomers during the period from October 20 to October 24.—Magnetic declinations and inclinations observed in Tunis by the Hydrographic Mission of 1884–86, communicated by M. Bouquet de la Grye. The results of these observations are tabulated for twenty-one places, whose latitudes and longitudes are also accurately determined.—On the

phosphites of ammonia, by M. L. Amat. The process is described by means of which the author has obtained the salt (PhO_3HO) NH_4O,HO, which has not hitherto been studied. It may be prepared very easily in beautiful crystals and in a perfectly pure state, which is rarely the case with phosphites.—On the production of the double carbonate of silver and potassium, by M. A. de Schulten. The carbonate of silver obtained by the action of an alkaline carbonate on the nitrate of silver is found to be sometimes yellow, sometimes white, while in most cases the white precipitate takes the yellow colour when washed with water. The experiments here described show that, as anticipated by the author, the white colour of the precipitates is due to a combination of the carbonate of silver with the alkaline carbonate, this combination being transformed by the water into a yellow carbonate by eliminating the alkaline carbonate.—On some salts of aniline, by M. A. Ditte. The salts here described are formed by metallic acids almost insoluble in water, or by energetic oxidants, and have been obtained by the process of double decomposition. They comprise a molybdate, a tungstate, a vanadate, an iodate, a chlorate, and a borate.—Formation of normal amylic alcohol in the fermentation of glycerine set up by *Bacillus butylicus*, by M. Ed. Charles Morin. Fitz has shown that, under certain conditions of temperature and environment, this Bacillus transforms glycerine into alcohols, glycol, and acids. To the normal ethylic and propylic alcohols determined in the products of the fermentation must now be added normal amylic alcohol, which may be easily extracted by distillation.—On a remarkable variety of mineral wax, by MM. G. Dollfus and Stanislas Meunier. The specimens here described came from Sloboda Rungorska, near Kolomea, in Austrian Galicia, where petroleum wells have recently been sunk. A rough analysis yields $H = 15, C = 85$, corresponding to the formula CH, with density 0·60.

BERLIN.

Physical Society, October 28.—Prof. von Helmholtz, President, in the chair.—The President gave a heart-felt address in memory of the late Prof. Kirchhoff, who was Vice-President of the Society.—Dr. Robert von Helmholtz showed and explained before the Society the experiments on vapour currents, of which he has recently given an account in *Weidemann's Annalen*. In his earlier experiments on the formation of mist he arrived at the same results that had been obtained by Aitken—namely, that the condensation of supersaturated aqueous vapour, as it forms a mist, takes place only at some nucleus which is provided ordinarily by the particles of dust in the air. His observations on vapour currents have, however, now shown that other conditions have an influence on the condensation. When a platinum wire heated red-hot by an electric current is brought near a current of vapour, the colour of the latter changes owing to an increased condensation. A similar result was obtained when the following agents were employed instead of the red-hot platinum wire, viz. the gases evolved from a hydrogen flame; the gases which rise from a glowing wire gauze; a metallic point from which electricity is making its exit; an electric spark; the vapours which rise from sulphuric acid; sal-ammoniac when formed in the current of vapour by the interaction of hydrochloric acid gas and ammonia. In all these last-named cases, where the condensation is facilitated, it is impossible to speak of any "nuclear" action. The speaker was of opinion that a supersaturated vapour, just as is the case with water cooled below its freezing-point, or a supersaturated solution of any salt, can be made to pass from its condition of unstable equilibrium by two means, either by some "nuclear" action or by a sudden vibration. Mist formation is the result of a "nuclear" action in those cases in which the atmospheric dust induces a condensation in the supersaturated vapour. The condensation must be regarded as the result of the sudden vibration in the other cases mentioned above. Although in these cases no truly mechanical vibration takes place, still the chemical processes involved in the production of the gases evolved by the flame, in the evaporation of the sulphuric acid, in the formation of the sal-ammoniac, at the point from which the electricity is making its exit, and in the electric spark, are to be regarded as so many sources of molecular tremors which upset the unstable equilibrium of the supersaturated vapour.—Dr. Dieterici gave an account of his experiments on the determination of the mechanical equivalent of heat by the indirect electrical method. He made this choice of method on account of the exactness with which electrical values can now be determined in absolute units. The speaker described the general arrangement of his experiments and gave a detailed account of the ice calorimeter which he used, as specially modified by himself. As the result of his series of measurements he obtained closely agreeing values for the mechanical equivalent of heat, namely 424·4 and 424·2 as the mean of each series, the highest and lowest values obtained differing but little from the mean of the determinations. When making his calculations the speaker took as the specific heat of water, the mean of the determinations made between 0° C. and 100° C. The statements which have been made respecting changes in the specific heat of water as dependent on changes of temperature differ so greatly with different observers that the mean values based on their results provide no constant factor; the speaker's determinations would have been considerably different had he taken as his basis any other value of the specific heat of water. He next compared the results of his experiments with those of earlier observers, and discussed the very marked differences in the values given for the specific heat of water at various temperatures. He thinks that the specific heat of water may best be determined by the electrical measurement of the mechanical equivalent of heat, and intends to investigate this question more fully at a later date.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Pen and Pencil in Asia Minor: W. Cochran (Low).—An Elementary Treatise on Light and Heat: Rev. F. W. Aveling (Relfe).—British and Irish Salmonidæ: F. Day (Williams and Norgate).—*Vega* Expeditionens, 2 vols.: A.E. Nordenskjöld (Beigers, Stockholm).—L'Atmosphère et Météorologie Populaire: C. Flammarion (Hachette, Paris).—Spezial Karte von Afrika, 2, 3, 4, 5 Lief. (Perthes, Gotha).—Guatemala; the Land of the Quetzal: W. T. Brigham (Unwin).—The Microscope in Theory and Practice, translated from the German of Prof. Carl Naegeli and Prof. S. Schwendener (Sonnenschein).—Reynolds's Experimental Chemistry, Part 4, Organic (Longmans).—Klima und Gestaltung der Erdoberfläche: Dr. J. Probst (Schweizerbart'sche, Stuttgart).—Beiträge zur Geophysik, i. Band: Prof. Dr. Georg Gerland (Schweizerbart'sche, Stuttgart).—Die Japanischen Seeigel, 1 Theil: Dr. L. Döderlein (Schweizerbart'sche, Stuttgart).—The Lake Age in Ohio: E. W. Claypole (Maclachlan and Stewart).—Gold-fields of Victoria, Reports of the Mining Registrars for Quarter ended June 30, 1887 (Melbourne).—Report on the Progress and Condition of the Government Botanical Gardens at Saharanpur and Mussoorie for Year ending March 31, 1887 (Allahabad).—Coleoptera; or, Beetles of South Australia: J. G. O. Tepper (Wigg, Adelaide).—The Answer to the Universal Question, What is an Earthquake? —Journal of Anatomy and Physiology, October (Williams and Norgate).—Journal of the National Fish-Culture Association, October.—Journal of the Chemical Society, November (Gurney and Jackson).

CONTENTS.

THURSDAY, NOVEMBER 17, 1887.

POLITICS AND THE PRESIDENCY OF THE ROYAL SOCIETY.

THE combination of vigorous intellect, profound knowledge, and scrupulous integrity, is not so common among our legislators, that a good citizen, whatever his political convictions, can have any feeling but one of satisfaction at the entrance into the House of Commons of the new member designate for the University of Cambridge. Prof. Stokes's foes (if indeed he have any foes), no less than his friends, will concur in attributing these qualifications to him. No man in the scientific world is, or deserves to be, more respected or more popular.

In that world many will doubtless find an additional source of congratulation in this public recognition of the merits of their colleague by the dominant political party in the University of Cambridge. And many will probably entertain the hope that the addition of another man of science to the three or four, who already occupy seats in the House of Commons, may do something towards the enlightenment and guidance of the House and of the Government, when scientific questions come under discussion.

In the minds of thoughtful men, more or less familiar with the realities of political and official life, however, it is probable that reflections of a less satisfactory nature may arise. They may regret that faculties which are so eminently fitted to serve science should inevitably be devoted to the interests of a party. Inevitably, because, with whatever high resolves the nominee of the Conservatives of Cambridge enters Parliament, he will find, before he has been there a week, that he is expected to do what the Whips bid him to do. And again such persons may think, not unreasonably, that Science is every day becoming more and more able to look after her own interests; and that, for her own honour and dignity, it is better that they should be neglected than that they should be promoted by back-stairs agencies. Moreover, experience may suggest that the deliberate judgment of the majority of scientific men, upon any question in which State intervention is called for, may be widely different from the view taken by this or that member of their body who happens to have a seat in Parliament; and that it is extremely undesirable that less legitimate methods of influencing a Minister should be substituted for the present fair and open mode of placing a case before him by responsible and authorized deputations.

But, whatever doubts may be entertained as to the service which has been, or can be, rendered to science by scientific members of Parliament, it is obviously within the right of every man to judge for himself whether he will become one or not. So far as Prof. Stokes is simply a very distinguished mathematician and physicist, it is for him, and for him alone, to decide between the claims of science, on the one hand, and those of political and ecclesiastical conviction on the other.

At the present moment, however, Prof. Stokes is something more than an eminent investigator and teacher: he is President of the Royal Society; and, as such, he enjoys all the prestige which is given by the fact that, in the eye of the public, he has the oldest, the strongest, and the most widely representative body of men of science in the country at his back. The President is the organ and mouth-piece of the Council of the Royal Society—a body which has frequent and important relations with the Government; and, as such, it may often be his business to represent to the Government the conclusions at which the Council arrives. It is therefore highly important that the freedom of the President's intercourse with Ministers should be in no way trammelled by his political relations.

It may be quite safely affirmed that Prof. Stokes's political and ecclesiastical views were not taken into consideration by those who placed him in the chair of the Royal Society. The last half-dozen of his predecessors, to go no further back, have sedulously abstained, during their occupancy of the chair, from holding office in any other Society, no less than taking part in any public, and especially political, action about which the opinions of the Fellows could be divided. Prof. Stokes has not followed this prudent example. Some little time ago he accepted the Presidency of a body of pronounced theological tendencies; and he now accepts the nomination of a no less pronounced political party, and, since our note upon his candidature appeared, he has issued an address in which he promises to devote himself to certain party objects.

It does not appear that Prof. Stokes has obtained, or, indeed, sought, the sanction of the Council or of the Society, at large, for this departure from precedent. For such it is, in spite of the fact that Sir Isaac Newton was a member of Parliament during his Presidency, and that many peers have occupied the chair. But it is obvious that a peer need not be a party politician; and, as regards the precedent of Sir Isaac Newton, it is enough to point out that the House of Commons of the end of the nineteenth century is a very different body from the House of Commons of the beginning of the eighteenth century. The position of an independent member has become impossible; and those who refer to Prof. Stokes's address will see that, whatever his first feelings may have been, he, now at any rate, does not propose to be anything but a staunch Conservative.

No doubt there are many staunch Conservatives in the Royal Society, but no doubt also there are many equally staunch Liberals and Radicals; and if it had entered into the imagination of the latter that Prof. Stokes would carry the prestige of the Presidency into the service of their political opponents, it may be doubted whether they would have voted for him. The same argument would apply with equal force if Prof. Stokes happened to be a Liberal. The question before us is one not of party, but of principle.

We are in the midst of a great political struggle, and it may be safely predicted that the force of party feeling will increase rather than diminish for years to come. If it is permissible that the President of the Royal Society may be a political personage, the minds of the Fellows on St. Andrew's Day will be divided between two sets of considerations. Not only will each ask, "Is A.B. the best man for the Presidency in the interests of science and of the Society?" which is the only question he ought to put; but he will ask, "Is A.B. of my politics, or the opposite?"

It is eminently true of political passion that a "little leaven leaveneth the whole lump"; once inoculate the Royal Society with that virus, and the poison will spread through the whole organism. The Council practically chooses the President: it will therefore be necessary to look to the politics of the Councillors. The Fellows elect the Council: have a care, therefore, to the politics of the new Fellows. We may yet see a politico-scientific caucus. Some years ago a most sagacious and experienced man of affairs in the United States was asked why, in drawing up the constitution of a new University, he had not given such persons as the Governor and Chief Justice of the State an *ex-officio* position on the governing body. "Ah," said he, with a shrewd smile, "if you only knew the trouble my colleagues and I have taken to render it impossible for any political person to have anything whatever to do with the administration of the University! We know to our cost that wherever politics enters corruption follows."

The records of the Royal Society tell us of more than two centuries of scientific life, fertile in good work and unstained by anything worse than an occasional outbreak of prejudice or jealousy. The only occasion on which it ever manifested a political bias was in the case of Priestley; and it has no reason to be proud of that episode.

The Society is now at the parting of the ways. Either it will continue its beneficent work for untold ages to come, untroubled by the transitory political and social storms raging around it; or, headed by politicians pledged to serve their party, it will gradually be dragged down into that miserable slough in which no capacity seems proof against the temptation to sophistical special pleading and no character strong enough to refuse degrading subserviency to party exigencies.

The occasion is grave and demands action. It is for the President, by the course which he may think fit to adopt, to determine what that action shall be.

THE STORAGE OF ELECTRICAL ENERGY.

The Storage of Electrical Energy. By Gaston Planté. (London: Whittaker, 1887.)

TO the author of this book we owe the use of lead plates instead of platinum plates in voltameters. His experiments showed that, after repeated charging and discharging of lead-plate voltameters, accumulators of energy were producible which might be employed in a great variety of useful ways. He showed that his accumulators might be charged in parallel by a few Bunsen or Daniell cells, and discharged in series. As his accumulators had small internal resistances, he was able to give to circuits either of small or great resistance very considerable supplies of electric power for short times, and as an experimenter he availed himself of this novel power in heating wires, melting beads of metal, and generally of observing effects produced by strong currents.

Many of the phenomena observed by him were new, and well worthy of being recorded, as they were recorded, in the proceedings of scientific Societies; and the present book, in addition to a fine portrait of the author, and many other engravings, and a dedication to the Emperor of Brazil, seems to be merely a collection of these papers of M. Planté, published between the years 1859 and 1879. In the first chapter of the book and part of the second we find an interesting account of experiments with various electrodes in voltameters, which led the author to use lead instead of platinum, and of the forms which the author gave to his cells, with directions for their formation, and speculations as to the chemical actions involved. The remaining twelve and a half chapters may be regarded as almost solely devoted to the "effects created by currents combining quantity with high tension"—to use the old-fashioned phraseology which Mr. Elwell, the translator, has thought fit to use upon the title-page—and to the author's speculations upon things in general.

The infancy of the electric accumulator lasted to 1879, its boyhood to 1883, and we may now be said to know it in its manhood. The advance since 1879, not only in our knowledge of the chemical and electrical actions going on in the accumulator, but also in our methods of applying this knowledge, has been quite as wonderful as the advance made in any other part of applied physics. Batteries of accumulators capable of driving boats 80 feet long, of driving numbers of tram-cars, of maintaining large installations of electric lights, are now in actual use. Plates of lead are now used as in 1879, but the salts of lead in contact with the metallic plates are attached mechanically, hundreds of devices having been tried and rejected or adopted in the last eight years for the purpose of obtaining great capacity and longevity. Of these great changes, the results of numerous, most costly, and carefully conducted experiments, made by scientific men, M. Planté tells us nothing. He was in charge of the accumulator in its infancy; it was taken away from him in 1879, and its subsequent history seems to be as unknown to him as the boyhood and early manhood of Harry Bertram were to Dominie Sampson.

The dominie looked upon his pupil, now grown to be a man, as if he were still a boy who was about to resume his childish studies, and in the same way it is probable that M. Planté regards the accumulator of 1887 as in no respect different from the laboratory toy with which he obtained such remarkable effects prior to 1879. M. Planté gives in this book what may be regarded as the history of the infancy of the electric accumulator; and it is obvious that if he had written it as charmingly as Mrs. Molesworth herself could have written it for the nursery, yet, with the misleading title which it possesses, he has given occasion to the ordinary reader to feel greatly disappointed. We are here assuming that M. Planté shares with Mr. Elwell the responsibility of publication, and also of change in the name of the book from that of the first edition—"Recherches sur l'Électricité"—published in 1879, which is the only French edition with which we are acquainted.

The technical terms used by the translator are not now so familiar to students as they used to be in the good old times when *strength*, *intensity*, *quantity*, and *power* of a current were synonymous with each other or with electromotive force.

It was this freedom in "the older electricity" which enabled statements like "The E.M.F. was thus found equal to 1·41, the current from the Bunsen cell being 1" (p. 17) to be enjoyed by readers. Other statements like

this: "We have found that the resistance of secondary cells of the various dimensions which we have used varied from 2 to 5 metres of a copper wire 1 millimetre in diameter" (p. 64), show that M. Planté sought for greater exactness in his measurements than many of his contemporaries during the infancy of the electric accumulator.

It was to be expected that in suggesting yet untried applications of secondary batteries the author should make statements which any student now knows to be erroneous. An example is to be found at p. 105, where it is suggested that, by using a secondary battery, two ordinary Bunsen cells might be enabled to work a continuous voltaic arc. As was also to be expected in such a republication of papers as this, many of which read like the contents of an inedited laboratory note-book, there are repetitions of the same facts and sentiments.

Unfortunately there is another resemblance to laboratory notes in much of the matter of this book which cannot be so readily forgiven. One often confides to one's note-book a speculation which is based on a very far-fetched resemblance between two phenomena. And it is quite possible to find in a note-book such a note as this (p. 198): "The experiment described above (158) in which a cloud of metallic oxide, torn from an electrode by the current, takes a spiral motion in the body of a liquid under the influence of a magnet, seemed of a nature to explain, in particular, the remarkable form of spiral nebulæ." Then follows a description of the nebulæ observed by "Lord Ross," and the further remarkable note: "In view of so striking a similarity, may it not be reasonably supposed that the nucleus of these nebulæ may be formed by a veritable electrical furnace; that their spiral form is probably caused by the presence of celestial bodies powerfully magnetized, and that the direction of the curve of the turns in the spiral must depend upon the nature of the magnetic pole turned towards the nebula."

This sort of thing may be found in the note-book of almost any laboratory worker, but it is astonishing to find that M. Planté has not only published it in the proceedings of a scientific Society, but actually publishes it again after he has had many years of leisure for reflection and for verification. These speculations occupy many chapters of the book. M. Planté describes some natural phenomenon, such as globular lightning, the formation of hail, water-spouts, cyclones, the aurora, atmospheric electricity, spiral nebulæ, or solar spots; he then begins to write on the vague analogy existing between this natural phenomenon and some isolated phenomenon observed by him in the laboratory, and after he has written some pages, the analogy becomes very indistinct; but he continues to write in the hope that if he writes long enough he may obtain clearer ideas. Of the same kind are his "views" of the nature of electricity. He finds that when successive intense currents are sent through fine wires, which are, of course, greatly heated, the wires lose their straightness in curious ways. It is very interesting to read about the observed phenomena, but unfortunately we have the author's speculations as well. He says (p. 247):—"The phenomena we have just described (313–20) are of a nature to throw some light on the mode of propagation of electricity. The molecular vibrations revealed by knots formed in a metallic wire, by the curious noise, and by a notable change in its cohesion under the influence of the passage of the dynamo-static current which we have just studied, must be produced in a lesser degree in conducting substances traversed by electric currents of very low tension. This vibration may be too feeble to be perceptible, but it is not the less real. We are then able to conclude that the electric movement must diffuse itself in substances after the manner of a purely mechanical motion, by a series of very rapid vibrations of the more or less elastic matter through which it passes."

He then goes on in his last chapter, without a thought of the possibility that very rapid heating of a not perfectly homogeneous conductor might explain his phenomena, to build up a theory of electricity from these isolated facts with the help of a few far-fetched analogies, and he publishes his theory without further verification. In spite of our great obligations to M. Planté, we feel that he has set the very worst example possible to the probable readers of his book, in publishing these vague speculations of his.

JOHN PERRY.

FRITSCH'S CRUSTACEAN FAUNA OF THE CHALK OF BOHEMIA.

Die Crustaceen der Böhmischen Kreideformation. Von Prof. Dr. Anton Fritsch und Jos. Kafka. Pp. 55. (Prague: Selbstverlag, in Commission von Fr. Řivnáč, 1887.)

THERE is probably no sedimentary deposit in the whole series of the stratified rocks with which one is more familiar than the Chalk. This is doubtless due to its peculiar whiteness, and to the fact of its occupying so large an area in our eastern and south-eastern counties, and its prominence in the coast-sections of Yorkshire, Kent, and Sussex, and the opposite coast of France; forming at Dover those white cliffs which gave to our shores their ancient name of Albion.

In the Cretaceous formation, however, we include a set of other beds, very dissimilar from the Chalk in appearance and composition, but which, on stratigraphical and palæontological grounds, seem to form a natural rock-system. These are known as the Upper Greensand, the Gault Clay, the Lower Greensand, and the Wealden Beds, comprising marls, sands, clays, and even fresh-water limestones. Without entering into details as regards the minor divisions, we may say that the major proportion of these deposits are marine, as shown by the organic remains contained in them. The Chalk itself, from its general purity, must have been formed in a deep and open sea; indeed, the researches which have been carried on in the North Atlantic Ocean show that the materials for a continuous bed of limestone with flint-nodules are now being deposited at depths of from 400 to 2000 fathoms, while many forms of life met with there are analogous to those of the Chalk.

That this old Cretaceous sea must have been of very wide extent is proved by the enormous area over which its sediments have been traced, as shown on our geological maps; whilst outliers and vast beds of

flint-gravel derived from the Chalk give evidence of a still wider region once covered by its waters, but whose deposits have since been removed by denudation.

The *white* Chalk, whence the name "Cretaceous" was taken, is almost wholly confined to the Anglo-Parisian area, where the system was first studied, but the formation, varying in lithological characters, may be followed from England into France, Belgium, Holland (Maestricht), Denmark (Faxoe), south of Sweden, Hanover, Brunswick, Saxony, Bavaria, Bohemia, Moravia, Switzerland, Austria, and the chain of the Alps, the Mediterranean Basin, including parts of Spain, south of France, Italy, Greece, Asia Minor, Sicily, and North Africa. This latter is the well-known "Hippurite Limestone" of the South of Europe, which stretches away to Persia and the Himalayas, and extends over the greater part of the continent of India. Cretaceous fossils have also been traced as far south in Africa as Natal.

The vastness of the Cretaceous system in North America far exceeds even our largest computation of its aggregate mass in the European area, being from 11,000 to 13,000 feet in thickness; whilst in our own hemisphere it probably does not exceed 7000 feet as a whole. It extends across the breadth of the North American continent, and over wide regions in South America, marked by many of the characteristic fossils of the Cretaceous rocks of Europe. But the evidence of contiguity to land in North America demonstrated by plant and animal remains far surpasses our own very limited records of shore and shallow-water conditions in Cretaceous times in Europe. Nevertheless we do possess at Aix-la-Chapelle, and in Saxony and Bohemia, Upper Cretaceous beds containing plant remains, such as leaves of *Acer*, *Alnus*, *Credneria*, *Cunninghamites*, and *Salix*, with Conifers akin to *Sequoia* and *Pandanus*, South African, and Cape *Proteaceæ*, and many Cryptogams, chiefly ferns, such as *Gleichenia*, *Lygodium*, *Asplenium*, &c. These have been dealt with elsewhere, as have also the Cephalopoda ("Cephalopoden der Böhmischen Kreideformation," von Dr. Anton Fritsch; Prague, 1872).

The present monograph presents us with descriptions and figures of seventy-two species of Crustacea obtained from eight localities and well-marked beds in the Cretaceous formation of Bohemia. These are divisible into Cirripedia (twenty-one species), Bivalved Entomostraca, Ostracoda (twenty-one species), Decapoda-Macroura (eighteen species), Decapoda-Brachyura (twelve species). The Cirripedia, with one exception, all belong to the stalked division (Lepadidæ), or "barnacles," eleven species being common to our own Chalk and Gault. In these are included two varieties of that most aberrant genus *Loricula*, first described by Sowerby from the English Chalk, and afterwards more fully by Charles Darwin. This pedunculated genus, by a retrograde development, no longer stands supported on its stalk, but lies prone, attached by one side to the surface of some shell, or other foreign body, its five rows of peduncular imbricating scales (over 100 in number) serving to form a dermal covering to the soft parts of the animal, which must have been distorted in its mode of growth somewhat as the flat-fishes (Pleuronectidæ) are modified as the result of their recumbent habits.

A *Balanus*, referred to a new genus (*Balanula* ?), is supposed to represent a sessile form of Cirripede. Such a form, *Pyrgoma cretacea*, was described from the Upper Chalk of Norfolk by H. Woodward in 1868 (see *Geol. Mag.*, vol. v. p. 258, pl. xiv. figs. 1-3), but the "acorn-shells," Sessile Cirripedes, mostly belong to the Tertiary and Recent periods, in which they attain a large development all over the globe.

The Ostracoda have been determined by Herr Joseph Kafka, Dr. Fritsch's assistant, in the Museum at Prague. Of the twenty species here treated of, five have been previously figured and described as new by Herr Kafka in the *Sitzungsb. K. böhm. Gesell. Wiss.*, Prag, 1885. The figures and woodcuts of the old species have been mostly taken from Prof. von Reuss's memoir on the Microzoa in Geinitz's "Elbithalgebirge," and the new species are here also figured in woodcuts, some of which leave much to be desired as to "finish" of characteristic features. Figs. 24 and 25 appear to belong to *Macrocypris*, and not to *Bairdia*. Fig. 26 has no relation to *Bairdia*, but may be a *Cytherella*. The representation of *Cythere reticulata*, Kf. (Fig. 32, *a*, *b*, *c*), has some peculiarities which better figures perhaps would clear up. Though not mentioned by Herr Kafka, ten of the species are found also in the English Chalk, and the others (excepting Fig. 32) have near allies in that formation in Western Europe. It is stated that in Bohemia the Ostracoda are mostly found in the Senonian stage. Only *Cytheridea perforata*, and four other species, come from the Turonian beds of Weissenberg.

Turning to the higher forms of Crustacea, the Decapoda (crabs and lobsters), only a single species, *Enoploclytia leachii*, Mantell, is recognized as being identical with our Chalk Crustacean fauna; but the genera *Hoploparia*, *Callianassa*, *Palæocorystes*, *Necrocarcinus*, *Etyus*, and *Astacus* are represented by corresponding species in the two areas. *Callianassa* is said to be represented by six species. This is a burrowing form, of which only the great chelate appendages are usually found fossil, or are brought up in the dredge from deep water, and it is extremely doubtful, judging from the author's figures, whether more than about three out of six of Fritsch's species can be maintained. One Greensand species occurs in Ireland, and the well-known *Callianassa faujasii* described eighty-eight years ago from the Uppermost Chalk of Maestricht. We have also a Tertiary form described from the upper marine series, Hempstead, Isle of Wight. All these species are very nearly related to each other.

Perhaps one of the most interesting forms described by Dr. Fritsch is his *Stenocheles esocinus*, the long slender-toothed chelæ of which agree closely with those of *Astacus* (?) *zaleucus*, W. Schm., a Crustacean dredged up in 1000 fathoms during the *Challenger* Expedition near St. Thomas in the West Indies.

The present work is illustrated by ten chromolithographic plates and seventy-two text figures.

This series of fine memoirs, which is being issued by Dr. Fritsch from the Royal Bohemian Museum, Prague, will certainly maintain the merit, and serve to enhance the reputation, of that great institution, which has, quite recently, been so well endowed by the magnificent bequest of the late Dr. Joachim Barrande, the historian and palæontologist of the Silurian system of Bohemia.

OUR BOOK SHELF.

Manual of Mineralogy and Petrography, containing the Elements of the Science of Minerals and Rocks. By James D. Dana. Fourth Edition, Revised and Enlarged. Illustrated by numerous Woodcuts. (New York: Wiley and Sons; London: Trübner and Co., 1887.)

THAT a new edition of this important and admirable manual has been issued will be good news to all interested in mineralogy, and especially to the teacher and student. The book, which now consists of 517 pages, is well arranged throughout, and contains, as all such books should do, a full index. The whole body of mineralogical science is here brought to focus, and the present edition, in that part of it relating to the description of minerals, is brought down to the year 1886, many new species described during the past six years being included. The chapter on rocks has been re-written, re-arranged, and enlarged, and many illustrations are new. We would suggest to the learned author that in the next edition a chapter on meteorites and their mineralogy would form an appropriate and much-valued addition.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

"A Conspiracy of Silence."

THE article which I contributed to the September number of the *Nineteenth Century*, on the Coral Islands of the Pacific, has done what I intended it to do. It has called wide attention to the influence of mere authority in establishing erroneous theories and in retarding the progress of scientific truth. The vehement assault made upon it in the current number of the same review by Prof. Huxley, and the article by Prof. Bonney in this journal, are to me gratifying evidences of success. But both of these writers are entirely wrong in the interpretation they put on a few expressions in my paper. They interpret these expressions as conveying imputations on the probity and honour of scientific men in the habitual and wilful suppression or discouragement of what they know to be truth. But there is nothing to justify this interpretation. I have made no such accusation, and if any one else were to make it I should join the two indignant Professors in repudiating it. Scientific men are not only as good as other men in this way, but generally a great deal better. Prof. Huxley has been irritated by some "anonymous sermon," which I have not seen and for which I am not responsible. He admits that it is in this anonymous production that the "slanders" against scientific men have taken the peculiarly offensive form; but he maintains that this unknown writer has been "inspired" by my article on Coral Islands. On the strength of this assumption—which may be true for aught I know—he goes on through some seven pages to dissect certain parts of my paper, and to read into it a great deal that is due to his own excitement and to nothing else.

I have no difficulty in expressing clearly and without any circumlocution exactly what I do mean, and what I have intended to say. Prof. Bonney interprets it very fairly, in abstract, when he says that the moral of my paper is, "Beware of idolatry." Some theory, hypothesis, or doctrine, is propounded by a great man. It becomes established, partly perhaps by certain inherent elements of strength, or at all events of attractiveness. But soon it stands unassailable, and unassailed, upon the vast foundations of general acceptance and admitted authority. It becomes what Prof. Huxley on a celebrated occasion, and with at least a momentary insight, called "a creed." The effect of such a position is tremendous. Some men who see cause to doubt are daunted. They keep silence. Others are prevented from even thinking on the subject. A few who do think, and who do doubt, and who do venture to express their doubts, are discouraged and discountenanced. A great many others take refuge in a suspended judgment, even after the production of evidence which, in the absence of a "creed" and of authority, would have been deemed conclusive. In all this there may be, and in general there is, nothing worse than timidity on the part of those who are the laggards, or the opponents, in some great advance. It is more difficult for some men than for others to face a prevalent opinion or an accepted doctrine. It is all very well to say, as Prof. Bonney says, that "to the man of science truth is a pearl of great price, to buy which he is ready to part with everything previously obtained." But scientific men are human. They are, I admit, immensely superior to the politicians, especially just now. But they have their failings, and everyone who knows the history of science must be able to call to mind not one instance only, but many instances, in which the progress of knowledge has been delayed for long periods of time by the powerful and repressive influences of authority, exerted in one or other of many ways.

My contention is that Darwin's theory on the origin of the Coral Islands is a case in point. I believed in it or accepted it, for many years, as others did. Prof. Bonney admits that I have described it not only fairly, but as forcibly as if I were still its advocate. This is exactly what I tried to do. I now hold that it has been disproved, and has been replaced by another theory quite as grand, and more in harmony with other natural laws which are of universal operation, but have been only lately recognized. I affirm, farther, that this new theory or explanation has been received with the timidity, the discouragement, the discountenance, and the obstruction which are characteristic in such cases. That Dr. Geikie has supported it, is most creditable to him. But his voice is not enough to disprove the truth of my contention. That Prof. Huxley and Prof. Bonney should be unable to make up their minds upon such evidence as has been before us now for several years is, in my opinion, a strong confirmation of the law which is operating upon them. There are some discoveries in science—some explanations of curious phenomena—which are self-luminous. They shine with their own light. The moment they are suggested, with a few cardinal and certain facts to illustrate them, they are their own proof. Everything that turns up speaks in support of them. My conviction is that such is the character of Mr. Murray's theory of the coral island formations in the Pacific.

Prof. Huxley challenges me to re-affirm with better proof the fact I allege—that Mr. Murray has met with discouragement. I respond at once to that challenge. I have seen the letter from Sir Wyville Thomson in which that naturalist urged and almost insisted that Mr. Murray should withdraw the reading of his papers on the subject from the Royal Society of Edinburgh. This was in February 1877. No special reason was assigned, but the terms of the letter indicate clearly that Sir Wyville dreaded some injury to the scientific reputation of the body of naturalists of whom he was the chief, and for whom, as connected with the *Challenger* Expedition, he was in some degree responsible. He had not himself at that time, I believe, fully accepted the new doctrine. But that would have been no sufficient reason for discouraging free discussion, if it were indeed as free as it ought to be. In my article I understated the delay which was thus occasioned. Three years, not two, elapsed

before Mr. Murray was at perfect liberty to advocate his views in the proper place, before a scientific body.

But the challenge of Prof. Huxley has brought to my knowledge a new bit of circumstantial evidence to the same effect, which is highly significant. Among the investigators of the Pacific corals no man has done better work than Dr. Guppy, Surgeon of H.M.S. *Lark*. Since my article was written, his volumes on the Solomon Group of islands have been published. The geological volume is an admirable memoir. It is the record of observations as patient, detailed, and conscientious as have ever been made on the great geological problem which is at issue. After his return home he was advised by Mr. Murray to offer a paper on his researches to the Geological Society of London. He did so in the spring of 1885. But his paper was refused—much to Dr. Guppy's disappointment. It was not orthodox. His facts effectually removed some difficulties in the way of Mr. Murray's theory—facts which in more than a corresponding degree were adverse to the theory of Darwin. As a consequence the Royal Society of Edinburgh has had the honour of receiving and publishing Dr. Guppy's most interesting memoir. As a Scotchman I am proud of this contrast. I make no accusation of wilful unfairness against the authorities of the Geological Society of London, of which my critic Prof. Bonney was, I believe, at that time the President. They did not consciously discourage truth. On the contrary, they probably smelt heresy. But if their minds had been free from this prepossession—if they had been alive to the breadth and sweep of the questions at issue, and open to receive with welcome the crucial evidence bearing upon them which is contained in Dr. Guppy's paper—the rejection of it would have been impossible.

As regards Darwin's own state of mind upon the subject, I can only say that my information was as good as that in the possession of Prof. Huxley. I am not struck by the perfect candour of his reference to Darwin's letter to Prof. Semper in October 1879. If he had quoted the very next sentence to that which he does quote, a very different impression would have been left on the reader's mind. But I attach no importance to this point. I prefer to believe that Darwin's mind was open to conviction, and to hope that others will follow his example.

ARGYLL.

The Theories of the Origin of Coral Reefs and Islands.

I WAS pleased to see Prof. Bonney's article on the Duke of Argyll's strictures on scientific men ("A Conspiracy of Silence," NATURE, November 10, p. 25). It is to be hoped that the rhetoric and methods of Parliamentary debate will not become common in scientific controversy. The Duke is, however, not the first who has tried to show "that if Darwin had lived he would with his well-known candour have been the first to admit the truth of Murray's theory," &c., &c. This I submit is a species of rhetoric which is out of place in scientific discussion.

It so happens that shortly after the appearance of Mr. Murray's paper "On the Structure and Origin of Coral Reefs and Islands," in NATURE, August 12, 1880 (p. 351), I had occasion to write to Dr. Darwin, and in my letter the following passage occurs, which I only quote to make Darwin's answer intelligible :—

"*September* 21, 1880.

"I think the theory Mr. Murray sets forth—that the cones or peaks, on which he considers atolls have been formed, have been levelled up by pelagic deposits, and thus brought within the limits of reef-building coral growth—a very far-fetched idea."

To which Darwin with his usual acumen replies :—

"*Beckenham, September* 22, 1880.

"I am not a fair judge, but I agree with you exactly that Murray's view is far-fetched. It is astonishing that there should be rapid dissolution of carbonate of lime at great depths and near the surface, but not at intermediate depths where he places his mountain peaks.

"Dear Sir, yours faithfully,
"CH. DARWIN."

As so far there appears to have been no *written* expression of Darwin's views published, this quotation may be of value.

T. MELLARD READE.

Park Corner, Blundellsands, November 11.

Earthquake at the Bahamas.

I AM instructed by the Meteorological Council to inclose copies of reports from the Resident Justice and Light-keepers of Inagua, Bahamas, relating to an earthquake on September 23 last, which you may think worthy of a place in NATURE.

ROBERT H. SCOTT, *Secretary.*

Meteorological Office,
116 Victoria Street, London, S.W.
November 11.

The Resident Justice at Inagua to the Colonial Secretary, Nassau. In re Earthquake at Inagua.

Resident Justice's Office, Inagua, September 27, 1887.

I HAVE to report that this island was visited by a severe shock of earthquake at 7 a.m. of the 23rd instant; the effect on the light tower, the keeper reports, was terrific, two nuts on the iron stauncheon of the smoke-stack were broken, and several cylinders. A portion of the stone wall around the Residency, and other private property, were thrown down in Mathew Town.

At 8.10 p.m. another shock was felt, no damage at the township; at the light station the cylinder on the lamp was broken, and the keepers were compelled to extinguish the light to prevent conflagration. A new cylinder having been placed in position, the light was again lit in about six or eight minutes after the accident.

At midnight another shock was felt, and the light-keeper reported next morning several cracks in mortar inside of the light tower; the light continued good.

Since the 23rd instant several light shocks have been felt, which keeps the people in a state of alarm.

We have had no arrival from Hayti and neighbouring islands, and it is feared that some of them have greatly suffered.

(Signed) G. R. McGREGOR, *Resident Justice.*

The Hon. Robt. Butler, Acting Colonial Secretary.

Principal and Assistant Light-keepers, Inagua, to the Inspector of Lighthouses, Nassau.

Inagua Light Station, September 29, 1887.

SIR,—I beg most respectfully to report for your information that this station and island was visited by several severe shocks of earthquakes on the 23rd, 24th, 25th, and 26th instants. The shock on the former date was felt at 7 a.m., which shook the tower and dwelling severely. Two nuts forming a part of fastening of iron rods in the upper part of lantern supporting upper barrel and smoke-pipe were wrenched off and smashed several cylinders.

The second shock, at 8.10 p.m., shook the tower very much, and smashed the cylinder on lamp. The light was then extinguished to prevent fire, which last about eight minutes [*sic*], when the light was again exhibited and kept burning bright and clear until daylight. There was another shock felt during the night, but not so severe. I noticed several cracks on the walls in the tower, which may be the mortar only. The latest shock was on the morning of the 26th at 1.3.

I am glad to say that the lamp and machinery are in good working order, but there will be slight repairs required.

The latest shock felt was at midnight of the 27th.

I also inclose the head of nut, the length of which is seven-eighths of an inch on inside.

I have, &c.,
(Signed) BYRON N. JONES, *Principal;*
CORNELIUS S. E. LOTMAN, *Assistant.*

The Inspector of Lighthouses.

RESEARCHES ON METEORITES.

I.

On October 4 I communicated to the Royal Society a preliminary note embodying some results I had obtained in observations on meteorites, undertaken with a view of obtaining additional information on some parts of the spectrum of the sun.

Some years ago I commenced a research on the spectra of carbon in connection with certain lines I had detected in my photographs (1874) of the solar spectrum. I have been going on with this work at intervals ever since; and certain conclusions to which it leads, emphasizing the vast difference between the chemical constitution of the sun and of some stars, recently suggested the desirability of obtaining observations of the spectra of meteorites and of the metallic elements at as low a temperature as possible.

I have latterly, therefore, been engaged on the last-named inquiries. The work already done, read in conjunction with the work on carbon, seems to afford evidence which amounts to demonstration on several important points.

The researches are still very far from complete, and the results must be given with great reserve, as the astronomical observations with which I have had to compare my laboratory work have been frequently made under conditions of very great difficulty.

A full report on the work, so far as it has gone, made to the Solar Physics Committee, which I have also communicated to the Royal Society, was read to-day, and I have received permission to publish part of it in this week's NATURE.

The general conclusions at which I have so far arrived may be stated as follows:—

I. All self-luminous bodies in the celestial spaces are composed of meteorites, or masses of meteoritic vapour produced by heat brought about by condensation of meteor-swarms due to gravity.

II. The spectra of all bodies depend upon the heat of the meteorites, produced by collisions, and the average space between the meteorites in the swarm, or in the case of consolidated swarms upon the time which has elapsed since complete vaporization.

III. The temperature of the vapours produced by collisions in nebulæ, stars without C and F but with other bright lines, and in comets away from perihelion, is about that of the bunsen burner.

IV. The temperature of the vapours produced by collisions in α Orionis and similar stars is about that of the Bessemer flame.

V. The line of increase of temperatures of the swarms of meteorites, and of subsequent cooling of the mass of vapour produced, and the accompanying phenomena, may be provisionally stated as follows:—

Sequences of Spacing and Temperatures (Provisional).

From Cold to Hot = Sparse to Dense Swarms.

	Spectrum of interspace. H.	C.	Spectrum of vapour of meteorite. *Radiation.*	*Absorption.*	Spectrum of meteorite. *Radiation.*
Nebulæ (without F)	Nil	Nil	Mg (500) ± 495	Nil?	Dimly continuous.
Comets 1866 and 1867	Nil	Nil	Mg (500)		
Nova Cygni after collision ...	Nil	Nil	Mg (500)... ...		
Stars with bright lines (without F)	Nil	Nil	Fe, Mn	Broad band 475	
Nebulæ (with F)	H	Nil	Mg (500) ± 495	Nil?	Continuous.
Stars with bright lines (with F).	H	Nil	Fe, Mn	D and *b* and other lines and bands	
Comets under mean conditions of collision	Nil	C	Mg(*b*)	Nil.	Continuous.
Comets at perihelion...	Nil	C	Meteorite lines.	(?)	
Stars, Class III.*a*	Nil	C		Meteorite flutings and lines	Vividly continuous.
Mixed swarms—					
R Geminorum	H	C	Meteorite lines.	Meteorite lines	
Nova Orionis at maximum.	H	C		Meteorite flutings and lines	
Condensation.					
Stars, Classes I. and II.			Continuous ...	High-temperature lines of substances present in meteorites	The radiation from individual meteorites now gives place to radiation from the interior vaporous and subsequently consolidated mass of the condensed swarm.
Subsequent Cooling.					
Stars, Class II. some stars, including sun ...			Continuous ...	K in excess	
Stars, Class III.*b*				Flutings of carbon ...	

VI. The brilliancy of these aggregations, at each (increasing) temperature, depends on the number of meteorites in the swarm—*i.e.* the difference depends upon the quantity, not the intensity, of the light.

VII. The existing distinction between stars, comets, and nebulæ rests on no physical basis.

VIII. The main factor in the various spectra produced is the ratio of the interspaces between the meteorites to their incandescent surface.

IX. When the interspace is very great, the tenuity of the gases given off by collisions will be so great that no luminous spectrum will be produced ("nebulæ" and "stars" without F bright). When the interspace is less, the tenuity of the gas will be reduced, and the vapours occupying the interspaces will give us bright lines or flutings ("nebulæ" and "stars" with F bright). When the interspace is relatively small, and the temperature of the individual meteorites therefore higher, the preponderance of the bright lines or flutings in the spectrum of the interspaces will diminish, and the incandescent vapour surrounding each meteorite will indicate its presence by absorbing the continuous-spectrum-giving light of the meteorites themselves.

X. The brighter lines in spiral nebulæ, and in those in which a rotation has been set up, are in all probability due to streams of meteorites with irregular motions out of the main streams, in which the collisions would be almost *nil.* It has already been suggested by Prof. G. Darwin[1]—using the gaseous hypothesis—that in such nebulæ "the great mass of the gas is non-luminous, the luminosity being an evidence of condensation along lines of low velocity according to a well-known hydrodynamical law. From this point of view the visible nebula may be regarded as a luminous diagram of its own stream-lines."

XI. New stars, whether seen in connection with nebulæ or not, are produced by the clash of meteor-swarms, the bright lines seen being low-temperature lines of elements the spectra of which are most brilliant at a low stage of heat.

XII. Most of the variable stars which have been observed belong to those classes of bodies which I now suggest are uncondensed meteor-swarms, or stars in which a central more or less solid condensed mass exists. In some of those having regular periods the variation would seem to be partly due to

[1] NATURE, vol. xxxi. p. 25.

swarms of meteorites moving around a bright or dark body, the maximum light occurring at periastron.

XIII. The spectrum of hydrogen seen in the case of the nebulæ seems to be due to low electrical excitation, as happens with the spectrum of carbon in the case of comets. Sudden changes from one spectrum to the other are seen in the glow of meteorites in vacuum tubes when a current is passing, and the change from H to C can always be brought about by increased heating of the meteorite.

XIV. Meteorites are formed by the condensation of vapours thrown off by collisions. The small particles increase by fusion brought about again by collisions, and this increase may go on until the meteorites may be large enough to be smashed by collisions, when the heat of impact is not sufficient to produce volatilization of the whole mass.

XV. Beginning with meteorites of average composition, the extreme forms, iron and stony, would in time be produced as a result of collisions.

XVI. In recorded time there has been no such thing as a "world on fire" or the collision of masses of matter as large as the earth, to say nothing of masses of matter as large as the sun; but the known distribution of meteorites throughout space indicates that such collisions may form an integral part of the economy of Nature. The number of bodies, however, subject to such collision is small, and must, it would appear, form but a small percentage of the celestial bodies, seeing that they must be consolidated.

XVII. *Special solar applications.*

α. The solar spectrum can be very fairly reproduced (in some parts of the spectrum almost line for line) by taking a composite photograph of the arc spectrum of several stony meteorites, chosen at random, between iron meteoric poles.

β. The carbon which originally formed part of the swarm the condensation of which produced the sun has been dissociated by the high temperature brought about by that condensation.

γ. The indications of carbon which I discovered in 1874 (Proc. R.S., vol. xxvii. p. 308) will go on increasing in intensity slowly until a stage is reached when, owing to the reduction of temperature of the most effective absorbing layer, the chief absorption will be that of carbon—a stage in which we now find the stars of Class III.*b* of Vogel's classification.

δ. At the present time it seems probable that among the chief changes going on in the solar spectrum are the widening of K and the thinning of the hydrogen lines.

Experiments upon which the Foregoing Conclusions depend.

A. Experiments upon carbon.

The main conclusions which may be stated here are that there are two systems of flutings which depend upon temperature only.

At low temperatures all compounds of carbon give a set of simple flutings, the brightest of which are at wave-lengths 4510, 4830, 5185, and 5610. At higher temperatures there is a series of compound flutings, the brightest edges of which are at wave-lengths 4380, 4738, 5165, and 5640. In the case of compounds of carbon with hydrogen there is an additional fluting at wave-length 4310, and this is the only criterion for the presence of hydrocarbon among the flutings shown on the map. (See Map 3.)

B. Experiments upon the luminous phenomena of the various metals volatilized in the bunsen burner and the oxy-coal-gas blow-pipe flame as compared with the phenomena seen at higher temperatures.

The main conclusions are that certain lines, bands, and flutings are seen in the bunsen burner, that a larger number is seen in the flame, and that the total number seen in the burner and flame is small.

The order of visibility in the bunsen is, roughly—

Lines ... { Mg, Na, Li, Tl, Sr, Ba, Ca, K, Mn, Bi

Bands { Ca, Sr, Ba

Flutings { Mg, Mn

All the observations both of bunsen and oxyhydrogen flame may be condensed as follows:—

In metals of the alkalies	Na K Li
,, ,, alkaline earths ...	Ca Sr Ba
In magnesian metals	Mg Zn Cd

In metals which yield acids	Bi Ti W
In copper metals	Cu Tl
In noble metals	Ag Hg
In earthy metals	Ce

The following table shows the positions of the principal lines, bands, and flutings seen in the spectrum of each of the metals examined, arranged roughly in the order of their intensities.

It should here be stated that as some of the researches have had to deal with feeble illumination small dispersion has been of necessity employed, and to make the observations along the several lines comparable a one-prism spectroscope has been so far used throughout. Hence the wave-lengths given are in all cases only approximate. With this proviso the lines observed have been as follows:—

Lines {

In bunsen—

Mg	5183, 5172, 5167, 4586, 5201.
Na	5889, 5895.
Li	6705.
Tl	5349.
Sr	4607.
Ba	5534.
Ca	4226.
Mn	5395.
K	6950.
Bi	4722.

Seen on passing from the temperature of the bunsen to that of the oxy-coal-gas flame—

Fe	5268, 5327, 5371, 4383, 5790, 6024.
Cu	5105, 5781, 5700.
Cr	5202, 5203, 5207, 5410.
Zn	4810, 4911.
Cd	5085.
Ni	5476.
Ti	5128, 5338.
W	5490, 5511.
Ag	5208, 5464.
Hg	5460.
Ce	5273, 5160.

Bands {

In bunsen—

Ca	5535, 6250, 6500, 6000.
Sr	6050.
Ba	5150, 5250, 5330, 4860.

Seen on passing from the temperature of the bunsen to that of the oxy-coal-gas flame—

Co	4710, 4920, 5170, 5460.

Flutings	*In bunsen—*	
	Mg	5000
	Mn	5580, 5860, 6145, 5340
	Seen on passing from the temperature of the bunsen to that of the oxy-coal-gas flame—	
	Ba	6010, 6350, 6480
	Cr	5360, 5570, 5800, 6040
	Fe	6150
	Cu	6050, 6130
	Zn	5460, 5680, 4985, 5140, 5340

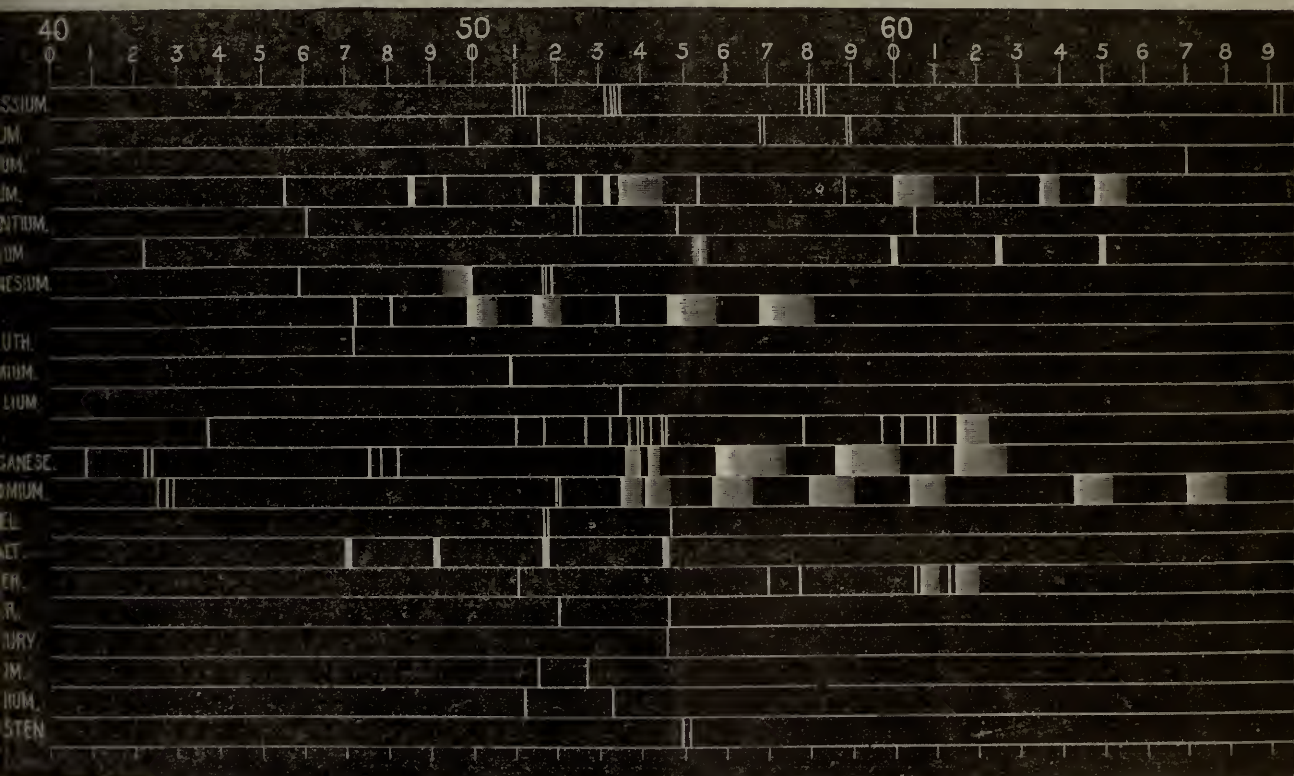
All the flutings, with the exception of magnesium, have their maxima towards the blue, and shade off towards the red end of the spectrum. (See Map 1.)

C. Experiments upon Mg at low temperatures.

I have again gone over the experiments already communicated to the Royal Society (Proceedings, vol. xxx. p. 27), and in addition have observed the spectrum of the metal burning in the centre of a large bunsen burner, in which case we get the line at 5201, and the fluting in the position of *b* without the fluting at 500. In the Bunsen as ordinarily employed the fluting at 500 far eclipses the other parts of the spectrum in brilliancy, and at this temperature, as already observed by Messrs. Liveing and Dewar (Proc. R.S. vol. xxxii. p. 202), the ultra-violet line visible is that at 373. Lecoq de Boisbaudran has observed the lines in the chloride at 4705 and 4483 ("Spectres Lumineux," p. 85).

D. Experiments upon the glow of Na and Mg in vacuum tubes.

A small piece of sodium, free from hydrocarbon, was placed in the lower limb of an end-on spectrum tube, and arrangements made for observing the spectrum of the gas evolved when the sodium was heated. Having first obtained as perfect a vacuum as possible, the sodium was gently heated, and the spectrum of the gas then gave nothing but the C and F lines of hydrogen. The pump being stopped and the sodium heated, a point was reached when C and F became very dim and were replaced by the structural spectrum of hydrogen.



Map 1.—Spectra of metals at the temperature of the oxy-coal-gas blowpipe.

In another experiment the sodium was replaced by a piece of magnesium along the end-on tube. The same process being gone through, similar phenomena were observed, but in the latter case there was a line at 500, in addition to the lines seen in the case of sodium.

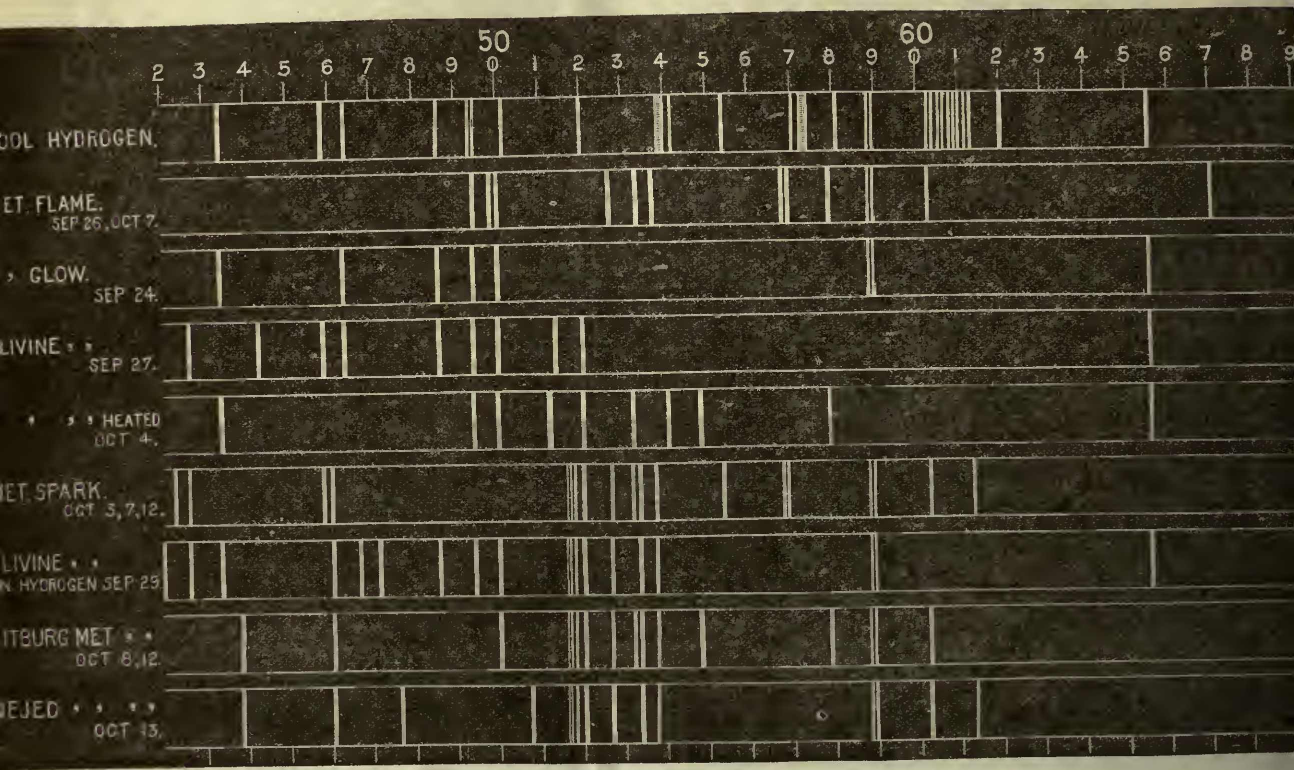
The important point, then, is the existence of a line at 500 in the spectrum when magnesium is heated, and the absence of such a line in the gas evolved from sodium under the conditions stated.

E. Experiments upon the conditions under which the C and F lines of hydrogen disappear from the spectrum.

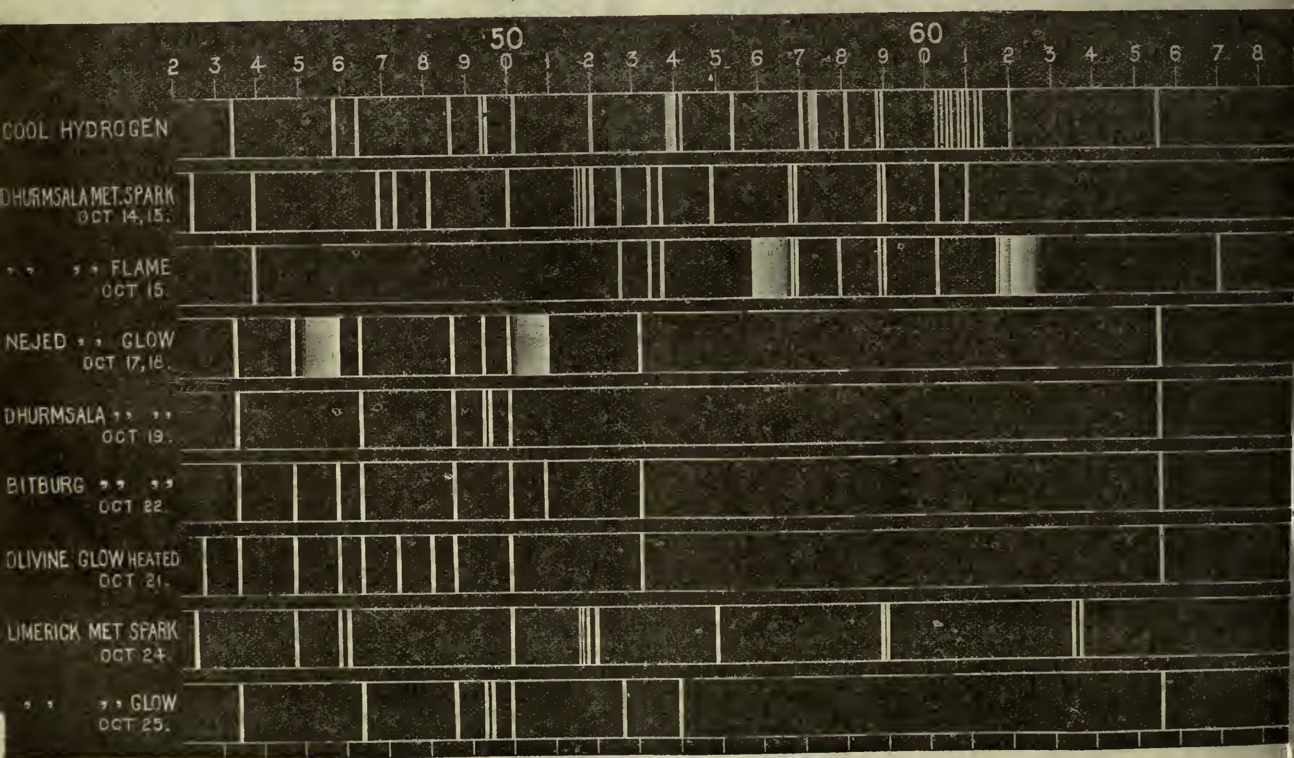
The association of the bright lines of hydrogen with nebulæ and many of the stars with bright lines and the so-called new stars points out at once that it is important to consider the various changes which hydrogen can undergo under various conditions of temperature and pressure. I pointed out many years ago that, when under certain conditions the spectrum of hydrogen is examined at the lowest possible temperature, the F line retains its brilliancy long after C disappears; and the fact that, after all the lines of hydrogen may be made to disappear from the spectral tube, the spectrum which remains visible, and is sometimes very brightly visible, is also due to hydrogen, has always been a matter of thorough belief in my mind, although so many observers, down even to M. Cornu not so very long ago, have been inclined to attribute it to the existence of "impurities."

I began to map the so-called structural spectrum at the College of Chemistry in 1869, but other matters supervened which prevented the accomplishment of this work. This, however, is a matter of small importance, because quite recently Dr. Hasselberg has communicated to the St. Petersburg Academy an admirable memoir on the subject, accompanied by a map (Mémoires de l'Académie Impériale, series vii. vol. xxx. No. 7, Hasselberg). The brightest portions of the structure spectrum are shown in Map 2.

The most convenient way of obtaining a supply of hydrogen for investigations of this kind is to use a little sodium which has never been in contact with hydrocarbon, or a piece of magnesium wire; to place them in the low end of a glass tube, one part of



MAP 2.—Spectra of olivine and meteorites under various conditions.



MAP 2A.—Spectra of olivine and meteorites under various conditions.

which can be used as an end-on tube, and then, after getting a vacuum so perfect that the spark will not pass, to slightly heat the metal. After a time the spectrum of hydrogen, sometimes accompanied by the low-temperature flutings of carbon, begins to be visible alike from the sodium and the magnesium.

If the vacuum has been very perfect to start with, the bright lines C and F will at first be visible without any trace of structure, and the hydrogen will be of a magnificent red colour. If now the action of the pump be stopped and the sodium be still more heated, a point will be reached at which the conductibility of the gas is at its maximum, and then, the jar not being in circuit, the structure-spectrum of the gas will be seen absolutely alone, without any trace of either C or F. The gradual disappearance of the F line is very striking, and when the bright line is out of the field the lines due to the structure seem to be enhanced in brilliancy.

The brightest part of the spectrum is then that near D; in the blue-green we have a line at 464 more refrangible than F, and then a doube line at 4930 and 4935; other less refrangible lines are seen. These are phenomena seen associated with sodium, but if we use the hydrogen produced from a piece of magnesium wire or from a crystal of olivine, under the same circumstances we find that so far as the lines of hydrogen go the phenomenon remains the same, but that there is then visible in the spectrum a line at 500, which has been recorded in the spectrum of magnesium under other conditions, not only by myself but by Dr. Copeland.[1]

F. Experiments upon the spectra of meteorites at low temperatures.

All the later observations recorded have been made on undoubted meteorites, fragments of which have been in the kindest manner placed at my disposal.

I. In the oxyhydrogen flame.

The observations gave in all only about ten or a dozen lines belonging to the metals magnesium, iron, sodium, lithium, and potassium, and two flutings, one of manganese, and one of iron.

II. With a quantity coil without jar.

The observations gave in all about twenty lines belonging to the metals magnesium, sodium, iron, strontium, barium, calcium, chromium, zinc, bismuth, and nickel, and four lines of unknown origin.

III. When heated in a vacuum tube when a current is passing along it.

A small piece of iron meteorite was inclosed in the middle of a horizontal tube, so that the spark might be made to pass through the tube and over the meteorite. After complete exhaustion has been obtained, the first spectrum observed when the tube, end on, is placed in front of the spectroscope, is a spectrum of hydrogen. The carbon flutings are only visible occasionally. If the meteorite then be very gently warmed by placing a Bunsen burner at some distance below the tube, the glow over the meteorite is seen to change its colour, and the line at 500 is constantly, and another line at 495, apparently exactly in the position of the second line of the spectrum of the nebulæ, is occasionally, seen. This line is more refrangible than the structure line of hydrogen in this region, which occupies the same position as the barium line. This, however, if the heating is continued, especially in the case of stony meteorites, is soon succeeded by a much more brilliant green glow, in which magnesium *b* and many other lines appear, now accompanied by the carbon flutings. The observations made under all the above conditions are shown in Maps 2 and 2A.

In these observations if a line in the meteorite spectrum were coincident with a metallic line, with the dispersion employed, in the absence of the brightest line of that metal, the line was regarded as originating from some other substance. Thus a line was sometimes seen at 5480, apparently coincident, with the dispersion employed, with the green lines of Sr and Ni; sometimes the brightest line of Sr at 4607 was absent, and it was then fair to assume that the presence of 5480 was due to Ni, but in the presence of 4607 it might be due to Sr.

[1] "To this table must be added 500·6 mmm. as the wave length of the first line in the great band of magnesium as determined by M. Lecoq de Boisbaudran from the spark-spectrum of the chloride of that metal, which evidently agrees with the flame-spectrum, in this region at least. It is worthy of note that this line almost absolutely coincides with the brightest line in the spectra of planetary nebulæ" (Dr. Copeland, *Copernicus*, vol. ii. p. 109).

Comparisons of the Foregoing Observations among themselves and with those made on various Orders of Celestial Bodies.

The discussions have taken, in the first instance, the form of comparisons of the different phenomena observed, and for this purpose all recorded observations of flutings and bright lines and dark lines in stars, comets, nebulæ, &c., have been carefully mapped in addition, all records having, when necessary, been brought to a common scale. Having these maps, I could then compare the totality of celestial observations with the laboratory work to which reference has already been made.

The following are among the comparisons already dealt with:—

I. The spectra of meteorites observed under the various conditions, chiefly considering magnesium, iron, and manganese, with the bright lines observed at low temperatures.

The main conclusions are:—

(1) That only the lowest temperature lines of Mg, Na, Fe, Cr, Mn, Sr, Ca, Ba, K, Zn, Bi, and Ni are seen in the meteorites under the various conditions. They are not all seen in one meteorite or under one particular condition; the details of individual observations are fully recorded in Maps 2 and 2A.

(2) That in the case of Mg the line most frequently seen is the remnant of the fluting at 500, while in a photograph the main ultra-violet line recorded is the one at 373, previously recorded under these conditions by Messrs. Liveing and Dewar. In the quantity spark other lines are seen, notably b_1, b_2, b_4, and 5201. The line at 500 was considerably brightened when the number of cells was reduced, thus showing it to be due to some molecule which can exist best at a low temperature.

(3) That in the case of Mn the only line visible at the temperature of the bunsen burner, 5395, is the only line seen in the meteorites.

(4) That the lines of iron seen in the meteorites are those which are brightest when wire gauze is burned in the flame. The chief of these are 5268, 4383, 5790, and 6024; it is possible, however, that the two latter are due to some substance, not iron, common to the gauze and the meteorites.

II. The spectra of meteorites generally, with the bright lines and flutings seen in luminous meteors, comets, and some "stars."

a. Luminous meteors.

With regard to the records of luminous meteors, it may be remarked that the observations, so far as they have gone, have given decided indications of magnesium, sodium, lithium, potassium, and of the carbon flutings seen in comets. The following quotations from Konkoly and Prof. Herschel are among the authorities which may be cited for the above statement.

"On August 12, 13, and 14, I observed a number of meteors with the spectroscope; amongst others, on the 12th, a yellow fireball with a fine train, which came directly from the Perseid radiant. In the head of this meteor the lines of lithium were clearly seen by the side of the sodium line. On August 13, at 10h. 46m. 10s., I observed in the north-east a magnificent fireball of emerald-green colour, as bright as Jupiter, with a very slow motion. The nucleus at the first moment only showed a very bright continuous spectrum with the sodium line; but a second after I perceived the magnesium line, and I think I am not mistaken in saying those of copper also. Besides that, the spectrum showed two very faint red lines."[1]

"A few of the green 'Leonid' streaks were noticed in November (1866) to be, to all appearances, monochromatic, or quite undispersed by vision through the refracting prisms; from which we may at least very probably infer (by later discoveries with the meteor-spectroscope) that the prominent green line of magnesium forms the principal constituent element of their greenish light."[2]

Again, later on in the same letter, Prof. Herschel mentions Konkoly's observation of the bright *b* line of magnesium in addition to the yellow sodium line in a meteor on July 26, 1873.

I again quote from Prof. Herschel:—

"On the morning of October 13 in the same year, Herr von Konkoly again observed with Browning's meteor-spectroscope the long-enduring streak of a large fireball, which was visible to

[1] Konkoly, *Observatory*, vol. iii. p. 157.
[2] Herschel, letter to NATURE, vol xxiv. p. 507.

the north-east of O'Gyalla. It exhibited the yellow sodium line and the green line of magnesium very finely, besides other spectral lines in the red and green. Examining these latter lines closely with a star-spectroscope attached to an equatorial telescope, Herr von Konkoly succeeded in identifying them by direct comparison with the lines in an electric Geissler-tube of marsh-gas. They were visible in the star-spectroscope for eleven minutes, after which the sodium and magnesium lines still continued to be very brightly observable through the meteor-spectroscope." [1]

The green line "*b*" of magnesium occurring as a bright line in luminous meteors indicates that their temperature when passing through our atmosphere is higher than that of the bunsen, and we may add of comets as generally observed, although some exhibit the *b* lines of magnesium and those of iron when at perihelion, as shown later on.

The two lines which Konkoly supposes are probably due to copper will, I expect, be found to be iron lines when other observations are made of the spectra of meteors.

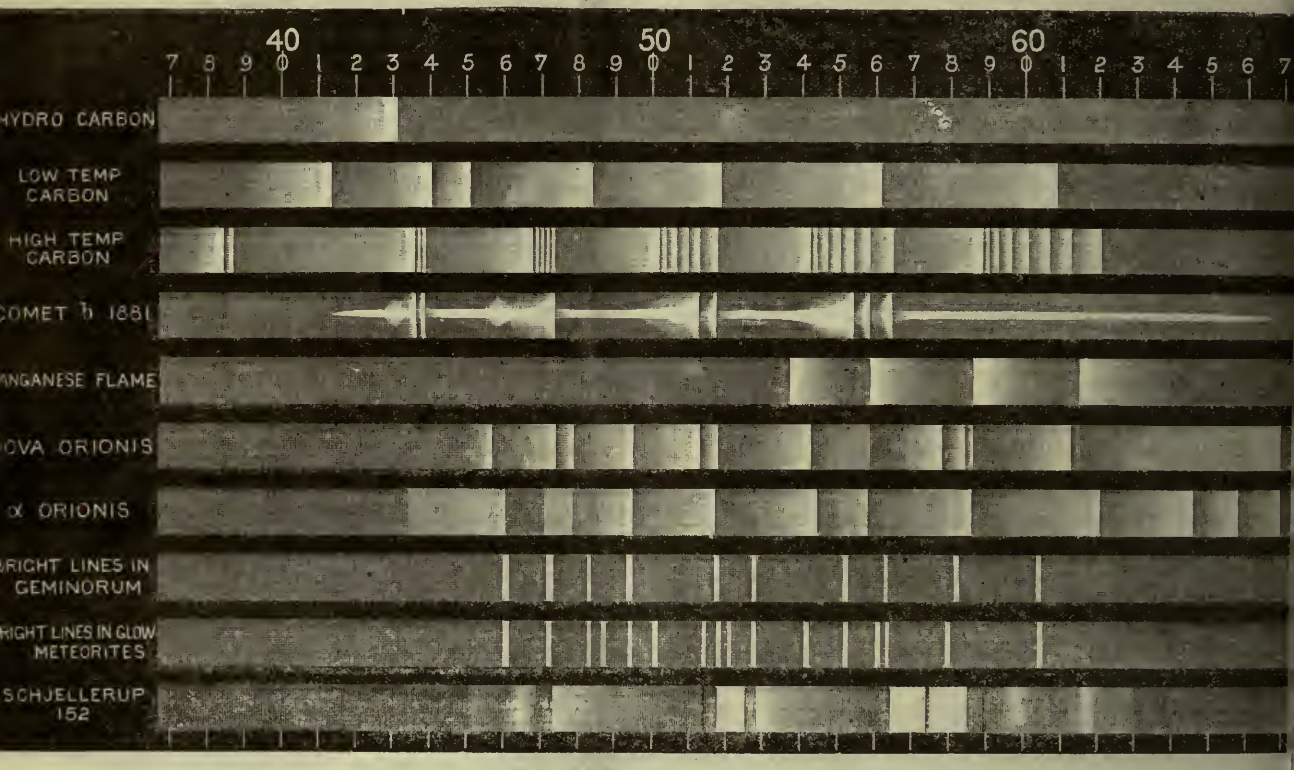
The main conclusions from this comparison are then: (1) that the temperature of luminous meteors is higher than that of the bunsen flame; (2) that the meteorites which produce the phenomena we are now discussing are hotter than those in the experimental glow taken generally; and (3) that in both cases flutings of carbon may be seen.

β. Comets.

When the meteorites are *strongly* heated in a glow-tube, the whole tube when the electric current is passing gives us the spectrum of carbon.

When a meteor-swarm approaches the sun, the whole region of space occupied by the meteorites, estimated by Prof. Newton in the case of Biela's comet to have been thirty miles apart, gives us the same spectrum, and further it is given by at all events part of the tail, which in the comet of 1680 was calculated to be 60,000,000 miles in length. The illumination therefore must be electrical, and possibly connected with the electric repulsion of the vapours away from the sun; hence it is not dependent wholly upon collisions.

Passing now from the flutings seen in cometary spectra, it is found that most of the lines which have been observed at perihelion are coincident with lines seen in experiments with meteorites,



MAP 3.—Comparison of flutings seen in the spectra of "stars" and comets with flutings of carbon, manganese, and zinc; and, in the case of R Geminorum, lines with remnants of flutings and lines seen in a meteorite glow. (The Zn fluting is at λ 544 in α Orionis.)

while the low temperature lines of Mg are absent. In the great comet of 1882, to which particular attention has been given on account of the complete record of its spectrum by Copeland,[2] the lines recorded were the D lines of sodium, the low-temperature iron lines at 5268, 5327, 5371, 5790, and 6024, the lines seen in the manganese spectrum at the temperature of the bunsen burner at 5395 and 5425, and a line near *b* which might be due to magnesium, or to a remnant of the carbon fluting. In addition to these there was a line at 5475, probably due to nickel, the absence of the blue strontium line indicating that it is not likely to be the green line of strontium. There were also four other lines less refrangible than D, the origin of which has not yet been determined. As the comet got further from perihelion the lines gradually died out, those which remained longest being the iron line at 5268 and the line near *b*. The absence of D before the disappearance of all the lines is probably to be accounted for partly by the greater brightness of the continuous spectrum in that region.

In the comets of 1866–67, when seen away from the sun, the only line seen was the one at 500.[1]

It is fair to myself to say that I was not aware of these observations when I began to write this paper. The fact of the line at 500 remaining alone in Nova Cygni made it clear that if my views were correct, the same thing should happen with comets. It now turns out that the crucial observation which I intended to make was made twenty years ago.

[1] Herschel, letter to NATURE, vol. xxiv. p. 507.

[2] *Copernicus*, vol. ii. p. 234.

[1] "In January 1866 I communicated to the Royal Society the result of an examination of a small comet visible in the beginning of that year (Proc. R.S. vol. xv. p. 5). I examined the spectrum of another small and faint comet in May 1867. The spectra of these objects, as far as their feeble light permitted them to be observed, appeared to be very similar. In the case of each of these comets the spectrum of the minute nucleus appeared to consist of a bright line between *b* and F, about the position of the double line of the spectrum of nitrogen, while the nebulosity surrounding the nucleus and forming the coma gave a spectrum which was apparently continuous" (Huggins, Proc. R.S. vol. xvi. p. 387).

In Comets *b*, 1881, and *c*, 1882, the only lines recorded were magnesium *b*; but, as before, the apparent absence of other lines might be due to continuous spectrum.

Of the five bands shown in Huggins's photograph of the spectrum of Comet Wells, taken with a wide slit, no less than three agree fairly in position with three lines seen in the spectra of meteorites. The wave-lengths of these are 4253, 4412, and 4769, and it is interesting to note that, so far, the origin of these lines is undetermined. The two remaining bands are at wave-lengths 4507 and 4634.

It is seen, then, that the spectra of comets—when their internal motions are relatively either slow or fast, and when therefore the number of collisions, and with them the heat of the stones in collision, will vary extremely—resemble the spectra of meteorites seen in glow tubes.

(γ) "Stars" with flutings which have been observed in the laboratory and in luminous meteors and comets.

The most prominent bright flutings of carbon are not only observed in luminous meteors and comets, but in stars of Class III.*a*, and in some "Novas," notably Nova Orionis. So far, then, these bodies may in a certain measure be classed with luminous meteors and comets. But there is an important difference in the phenomena, for we have absorption as well as radiation. The discussion shows that the dark (or absorbing) flutings in these bodies are partly due to the absorption of light by the most prominent flutings of Mn and Zn, seen at low temperatures. This inquiry is being continued.

We have, then, in these bodies a spectrum integrating the *radiation* of carbon and the *absorption* of Mn and Zn vapour.

The law of parsimony compels us to ascribe the bright fluting of carbon in these stars to the same cause as that at work in comets, where we know it is produced by the vapours between the individual meteorites or repelled from them.

Hence we are led to conclude that the absorption phenomena are produced by the incandescent vapour surrounding the individual meteorites which have been rendered intensely hot by collisions.

These stars, therefore, are not masses of vapour like our sun, but clouds of incandescent stones.

We have here probably the first stage of meteoritic condensation. J. NORMAN LOCKYER.

(*To be continued.*)

FAIRY-RINGS.

THE rains have come, and we have heard from all sides of the prolific crops of mushrooms and toadstools—paddock-stools, as they are termed in some northern districts—which have been springing up in the meadows and woods of England, Wales, and Scotland. Not only is surprise evinced at the marvellously rapid up-growth of these fungi, for the popular mind may well be amazed at that until a knowledge of the biology of these plants is more universal, but country people and dwellers in towns alike exclaim at certain other phenomena associated with their growth in the fields, and at none, perhaps, so much as what have been known from of old as "Fairy-rings" in England, *Hexenringe* and *Cercles de sorcières* on the Continent. Now fairy-rings, like very many other poetical objects, have of late years undergone the process of being explained away to an extent which, although it in no way removes the beauty from them, demands from us an admiration of a more stimulating and healthful character than the old awe which they inspired was capable of producing.

Disbelief prevails regarding Prospero and the beings that

> "By moonshine do the green sour ringlets make,
> Whereof the ewe not bites;"

and

> "whose pastime
> Is to make midnight mushrooms."

Fairy-rings are more or less regular and complete rings of grass, sharply distinguished from the ordinary grass surrounding them by means of their darker hue, more luxuriant growth, and other characters; in spring or autumn they are to be found with vigorous growths of mushrooms or toadstools springing from their outer margins, and the centre of the ring is often marked by a very poor crop of withered-looking herbage.

Before proceeding to give an account of the modern explanation of these remarkable objects, a few statements may be made as to their sizes, structure, and occurrence.

They are not always complete or regular rings, but may be parts of circles or ovals, or mere wavy strips. Nor are they always provided with the outer belt of fungi, though the rule is that a good season sees them so accompanied; if not, they do not remain long. In the typical cases, where the ring is annually provided with its fringe of fungi, it may go on increasing in size for years: records exist of rings which have been known to go on flourishing for forty or sixty years, and large rings on a hill-side could be seen from a considerable distance.

As to their sizes, they are known to commence as very small patches, but specimens have been measured as much as 60 feet and more in diameter. Indeed one observer refers to a fairy-ring which was nearly 100 feet across. While regarding these cases as rare extremes, it is well known that rings 12–20 feet in diameter have often been recorded, and, as we shall see, these must be several or many years old.

Although fairy-rings are usually noticed in meadows and on pasture lands, they are found on hills as well as in valleys, on dry soil as well as on wet, in woods and on heaths, and even in rocky places and situations near the sea. Perhaps the only generalization possible in this connexion is that they do not occur on highly-cultivated rich land.

On regarding carefully a typical fairy-ring, it may be found to present the following characters:—The central area, encompassed by the dark-green ring, consists of poor or even withered herbage—it may be of inferior grasses alone, or of these mixed with other plants. Then comes the band of luxuriant grass forming the ring proper: the grass composing this may be of more than one kind—*e.g. Lolium perenne* (the perennial rye-grass), *Dactylis glomerata* (the cock's-foot grass), and *Bromus mollis* (the soft brome) are common.

These grasses are rank, tall, and of a distinctly darker, bluer green hue than the rest; it is their coarseness, height, and especially the deeper colour, which render them so prominent. Fringing this ring, at the proper season, are found the spore-bearing heads of the Agarics *i.e.* the mushrooms or toadstools as the case may be; and if the observer digs carefully below the soil, he will find that these Agarics spring from a felted mass of root-like threads, the mycelium of the fungus. Then, outside all, comes the general herbage of the pasture, or whatever it may be: this is often scanty, indicating poor soil, and in any case is less luxuriant and lighter in colour than the rank herbage of the ring itself.

As with the herbage composing the rings, so the Agarics fringing them may be of different kinds. In the autumn the fairy-rings of this country and on the Continent commonly contain *Marasmius oreades*, Fr., a small pale mushroom with cream-coloured gills, and much esteemed as an esculent. It has a somewhat strong aromatic odour, and its mycelium is attached to the roots of the grasses among which it grows. It must not be confounded with certain acrid species allied to it.

The common mushroom (*Agaricus campestris*, L.) is also frequently found in large circles, fringing more or less complete fairy-rings. Among other forms may be mentioned the gray *Agaricus terreus*, Schoeff, not uncommon in beech- and fir-woods; the "parasol mushroom" (*Agaricus procerus*, Scop.), also not uncommon in fir-woods and pastures, and spoken of as one of the best of the esculent forms; also *Agaricus personatus*, Fr., with a lilac or purple stem. This is a late form,

good to eat, and called the "Blewit." *Agaricus subpulverulentus*, Pers., is also not uncommon, and several others are known.

In the spring, fairy-rings have been found containing *Agaricus gambosus*, Fr., an edible mushroom known in England as the "St. George's mushroom," and much esteemed on the Continent.

There are also other forms, several of them poisonous, or at least inedible or dangerous; and even puff-balls are known to be associated with fairy-rings.

And now we come to the question, How do these fairy-rings arise and increase? It cannot be wondered at that the people of earlier days, wishing to explain a phenomenon which none could overlook, sought for satisfaction in their myths and folk-lore, and believed them to be "caused" by fairies and elves and other mystic beings of the woods and fields, dancing in circles beneath the moonlight, and enchanting the ground into a richness which it did not previously possess.

Then came the era of science, and people were dissatisfied with beliefs, and in course of time the followers of De Candolle at least tried to solve the problem according to what was known of Nature. It was at least necessary to explain (1) why the centre of the ring is so poor, (2) why the fungi are confined to the margin, and (3) why the ring goes on enlarging, as continued observation showed that it did.

The first theory of any merit was, that the "ring" takes its origin from a single mushroom, which sheds its spores from the gills down on to the ground around the thick stem: this necessarily produces a ring of spores, as the stem dies down in the centre. Now the physiologists of those days believed that a plant excretes into the soil at its base substances which are harmful to its further development, and so, they argued, the soil on the inside of the ring of spores is poisoned, as it were, and only the outer spores produce new plants. The new mushrooms come up in a ring, and in their turn shed spores in a ring of rings; but since the soil on the inside of all these rings is poisoned by the excreta, only the outer series can germinate and grow, and thus a new ring arises next season, and so on. But, it was thought, though the excreta are injurious to the growth of the same plant (the fungus in this case) in that particular soil, other plants can grow there (in the present instance, grasses), and so a ring of rank grass follows on, which in its turn spoils the soil for its own kind as it increases.

Now it has to be admitted that there was much ingenuity in this hypothesis, and it was maintained for some time; until, in fact, physiologists had to give up the excretion theory as not in accordance with observed facts.

Then followed the beginnings of the celebrated doctrine of the rotation of crops, and the facts accumulated about fairy-rings had to be looked at again. They had become too much for the excretion theory; how did they look when regarded from the new point of view? First, however, we may bear in mind the fact noticed by several observers. When two fairy-rings gradually extend so as to interfere, the green circles coalesce and form a single ring: evidently the conditions of the soil in the wake of the advancing ring are such that the grass of another advancing ring cannot go on luxuriating there. It is true this fact was as easily made use of by those who maintained the excretion theory as by those who advanced the theory we are now going to examine.

It gradually came to be recognized that the reason one species of plant cannot be continually grown on the same soil was not because the first crop poisons the soil by leaving injurious excreta behind it, but because it *takes away* certain mineral substances in such proportions that too little is left for the well-being of a second crop of the same species; in other words, it *exhausts* the soil of certain necessary ingredients. A crop of some other species may be raised on the partially exhausted soil, however, provided it is a plant which does not need the materials now deficient, in such large quantities as its predecessor. This is, roughly sketched, the *rationale* of the doctrine of the rotation of crops, and it was subsequently suggested that the "fairy-rings" we are considering are a natural illustration of this. The vegetable physiologists then came to the conclusion that the fungus causes the fairy-ring by exhausting the soil of certain substances which are necessary to its existence, and is only able to produce continued crops by extending centrifugally into soil which still yields these substances: the grass, however, does not need these substances in such large proportions, and so follows the fungus. But, as we have seen, the grass which immediately follows the fungus is particularly rank and luxuriant, and it was necessary to find an explanation for this fact. It was then suggested that the dying mycelium of the fungus acts as a manure for the grass to feed upon, and until this is exhausted the growth is peculiarly rich and rampant.

Before leaving this part of our subject, it should be pointed out that Dr. Wollaston, in an essay on fairy-rings published in the Philosophical Transactions of the Royal Society so long ago as 1809, ventured on the explanation that the fungi spread in rings, because the soil was, by their mycelium, progressively "exhausted of some peculiar pabulum necessary for their production. . . . An appearance of luxuriance of the grass would follow as a natural consequence, as the soil in the interior of a circle would always be enriched by the decayed roots of fungi of the preceding year's growth."

Meanwhile, the physiology of plants was passing into a more scientific phase of existence, and the beginnings of modern agricultural chemistry were made; and in 1846 an important contribution to our knowledge of fairy-rings was afforded by Way, who chemically analyzed the soil, the herbage, and the fungi of some of these curious formations. This chemist found that the fungi of his fairy-rings were remarkably rich in phosphoric acid and in potash; and that they also contained relatively large quantities of nitrogen. We know now that this is true of fungi generally, but these facts were by no means so well understood at that time. Way also analyzed the grasses composing the ring, and found that they also contained a larger proportion of phosphoric acid and potash than the herbage in the neighbourhood, but by no means so much as the fungi: the grass also contained considerable quantities of nitrogen.

The net result of these investigations was to explain fairy-rings as an illustration of the rotation of crops, but of course putting the explanation on much firmer grounds. Way also pointed out that as the rank green grass was cut or otherwise removed, valuable ingredients (phosphorus, potassium, alkalies, &c.), were removed with it, and so the crops of grass further inwards become poorer and poorer, accounting for the bare patches often found inside the dark ring.

Messrs. Lawes and Gilbert, whose magnificent experiments on the vegetation of agriculture will never be forgotten, supported the above view of the matter, and showed that the dark-green colour of the rank grass is due to the relatively large quantities of nitrogen. It was at this time (about 1850) customary to suppose that plants obtained their nitrogen from the atmosphere, a view now known to be erroneous from the brilliant researches of Boussingault, and of Lawes and Gilbert themselves. On this supposition the extraordinary accumulation of nitrogen (in the fungus and rank grass) was thought probably due to a power on the part of the fungus of taking nitrogen from the air. Subsequently the whole matter was again taken in hand by Messrs. Lawes and Gilbert, and the results published in the Journal of the Chemical Society, 1883.

The chief additional facts may be summarized as follows:—The fungi remove large quantities of carbon, nitrogen, and especially phosphoric acid and potash, from the soil. The soil inside the ring contains less nitrogen than that under the ring, and this again less than the soil outside the ring; a gradual exhaustion of nitrogen, then, is taking place as the fungus and rank grass extend the ring centrifugally, and this is promoted by the removal of the grass.

These observers also demonstrated the spread of the mycelium: it is in greatest abundance just below the outer edge of the ring. They conclude that the fungus has powers of obtaining nitrogen from compounds in the soil which are not available to the roots of the green herbage, but after the decay of the fungus mycelium the grasses can avail themselves of part of the nitrogen. The grasses—being plants containing chlorophyll—of course obtain their carbon from the carbon dioxide of the atmosphere; but the fungus—equally of course, in the light of physiology—obtains its carbon from some organic substances in the soil. The accumulation of phosphoric acid and potash has already been accounted for.

We may now sum up, then, the rational explanation of these curious fairy-rings as follows.

A mushroom spore may be supposed to start its growth in or beneath the dung of cattle, or a bird, on poor soil; the first crop of mushrooms, produced from the mycelium to which the spore gave rise, exhausts the soil of available carbon, nitrogen, phosphorus, potash, and other substances, storing all it can get in its own substance. The mycelium extends centrifugally "into fresh fields and pastures new," and the next crop of mushrooms arises at a distance from the centre; and so the growth proceeds. The grasses, among the roots of which this extension is going on, now avail themselves of the rich manure afforded by the decomposition of the older mycelium, and a struggle for existence is set up which results in the victory of the coarsest and rankest-growing species. These in their turn exhaust the available supply, and if cut it is removed in their substance: no wonder, then, that the inner parts of the area are poor, and support little or no herbage.

Messrs. Lawes and Gilbert's researches also showed that if the growth of the herbage is promoted by means of manures containing much available nitrogen the fungi are found to suffer, and the "fairy-ring" may be brought to an end. Again, unfavourable seasons of drought may cause the death of the mycelium, and rings which have flourished for years be thus destroyed.

We have attempted in this article to give a complete explanation of the rise and progress of "fairy-rings," as afforded by modern science. That much is clear which was previously obscure will have to be conceded; but are all the facts covered by the explanation? There are some inquiring spirits who are never satisfied with an explanation, and we run the risk of being classed among these malcontents, but there are one or two curious little points which still obtrude themselves upon our attention.

There is, in the first place, some difficulty in realizing how the fungi manage to obtain their large supplies of carbon and nitrogen and other elements from poor shallow soil, in the absence of larger quantities of organic matter than may occur: there is, in fact, considerable difficulty about the whole question of the nutrition of the fungus. A second point is that we find the ultimate filaments into which the mycelium of the fungus breaks up becoming lost among the roots of the grasses; and if the latter are carefully washed and examined with the microscope, their fibrils and root-hairs can be seen to be infolded by delicate hyphæ, and in some cases the root-hairs are pierced by them. We do not know that this has been demonstrated before, but we find it the rule with *Marasmius*, and have already succeeded in detecting something of the kind in other forms.

Now this looks very like parasitism; and we are tempted to pause before accepting the last explanation of fairy-rings as conclusive, or covering all the facts. It may be, in fact, that the hyphæ of the fungus stimulate the roots of the grasses to increased activity: this would account for the rampant growth and the result of the struggle for existence. Subsequently the hyphæ kill the grass-roots—or at any rate those of some species—which accounts for the bare patches in some rings. It also easily explains the sources of the carbon and nitrogen, if the hyphæ absorb nutritive materials from the hard-working grass-roots. This being the case, fairy-rings become still more interesting, since they afford an illustration of symbiosis of a peculiar kind, at any rate during part of the time that the grass and the fungus are in contact; and it seems not improbable that the theory of the formation of fairy-rings will have to be modified somewhat as follows.

A fungus-spore starts its mycelium among the roots of the grasses, and the hyphæ obtain a hold on some root-hairs and fibrils; the mycelium thus parasitic on the roots reacts in a stimulating manner on the latter, and we have a symbiotic relationship established between the fungus and the host. The consequence is that both flourish, and become rampant. It may be that only some grasses are thus stimulated, or even attacked, and this will affect their struggle for existence, and result in the selection of a few coarse forms. In time the hyphæ or the roots get the upper hand, and this is expressed in the survival of the grass, or its decay; in some cases it is clear that hyphæ are living at the expense of dead and dying roots.

However, until the results of investigations at present going on are set forth more at length, it is impossible to say which of the above explanations is the true one; in any case, the attachment of fungus hyphæ to the living grass-roots needs explanation, and it must also be allowed that at present we have no satisfactory theory to account for the nutrition of these rampant mycelia. But this is not the place to do more than point out how interesting the subject is, and how promising a field for further research it offers.

NOTES.

MR. W. BATESON, Fellow of St. John's College, Cambridge, who has just returned from a zoological expedition to Central Asia, and is well known for his researches on *Balanoglossus*, has been awarded the Balfour Memorial Studentship in Animal Morphology.

THE second meeting of the newly-formed Anatomical Society of Great Britain and Ireland will be held on Tuesday, November 22, at University College, Gower Street, at 5 p.m. The following papers will be read:—Prof. Sir William Turner, F.R.S., (1) "Variations in the Hippocampus Major and Eminentia Collateralis," by Robert Howden, and (2) "A Metallic Body in the Spinal Canal," by David Hepburn; (3) "Minute Anatomy of Clarke's Column in Spinal Cord of Man, the Monkey, and the Dog," by Dr. Mott; (4) "The Arteries at the Base of the Brain," by Prof. Bertram C. A. Windle; (5) "Note on the Functions of the Sinuses of Valsalva and Auricular Appendices, with some Remarks on the Mechanism of the Heart and Pulse," by Mayo Collier. A number of interesting exhibits are also announced.

ON Tuesday evening the second part of an important paper upon the causes of accidents in mines and the development of measures and applications for combating or avoiding them was read by Sir Frederick Abel at the Institution of Civil Engineers. The first part of the paper was read in May last, at the close of the session. Sir Frederick's ideas will be discussed at the meeting of the Institution next Tuesday.

We are glad to hear that the Scottish University Extension Scheme is likely to prove successful. A brilliant start has been made in Perth, where Dr. H. R. Mill is giving a course of lectures on physiography to a class of over 240 students.

Some time ago it was arranged that three lectures on "Heredity and Nurture" should be delivered at the South Kensington Museum, on behalf of the Anthropological Institute, by Mr. Francis Galton, President of the Institute. We are requested to state that these lectures have been postponed in consequence of Mr. Galton's indisposition.

Prof. J. McK. Cattell's paper on "The Psychological Laboratory at Leipzig," to be read before the Aristotelian Society on the 21st, will contain an account of the aim of experimental psychology, of the Leipzig Laboratory, and of the researches which have been carried on and are being carried on in it. The paper will be published in the January number of *Mind*.

The borings in the Delta of the Nile carried on by the Royal Society have been brought to a standstill by the breaking of the pipe. The depth reached is over 324 feet, still without the solid rock being found. It is possible that the work may be recommenced upon a larger scale.

Several years ago three Russian "lady doctors" started at Tashkend a consulting hospital for Mussulman women. From the beginning the experiment proved a success, and the popularity of the hospital has been increasing ever since. During the last twelve months no fewer than 15,000 consultations have been given.

The Russian Consul at Kashgar writes to the Russian Geographical Society that his endeavours to obtain from the Chinese authorities permission to erect a memorial to Adolf Schlagintweit on the very spot where Schlagintweit was killed have not been successful. The memorial will be erected in the Russian cemetery, where it will be at least protected from injuries.

The money necessary for sending out M. Wilkitski to make pendulum observations in Novaya Zemlya has been granted by the Russian Geographical Society. He will be accompanied by a naturalist, M. A. Grigorieff.

The Moscow Society of Naturalists invites those scientific bodies which would like to receive, in return for their own publications, the series of the Moscow *Bulletin*, to communicate with the Secretary of the Society.

Reports from Bergen, in Norway, seem to indicate that another great rush of herring under the west coast may be expected this winter, similar to those which have taken place periodically during the last two centuries through some unknown cause. The two greatest rushes on record were those of 1740 and 1807.

During a hailstorm at Mors, in Denmark, a few days ago, a flash of forked lightning—the only one occurring—struck a farm, and, having demolished the chimney-stack and made a wreck of the loft, descended into the living-rooms on the ground-floor below. Here its career appears to have been most extraordinary; all the plaster around doors and windows having been torn down, and the bed-curtains in the bed-rooms rent to pieces. An old Dutch clock was smashed into atoms, but a canary and cage hanging a few inches from it were quite uninjured. The lightning also broke sixty windows and all the mirrors in the house. On leaving the rooms it passed clean through the door into the yard, where it killed a cat, two fowls, and a pig, and then buried itself in the earth. In one of the rooms were two women, both of whom were struck to the ground, but neither was injured.

The last two numbers of the *Folk-Lore Journal* (vol. v. Parts 3 and 4) exhibit very varied fare, and show how this interesting Society is gradually embracing the whole world. Side by side with Miss Courtney's Cornish folk-lore, we have Mr. Mitchell-Linne's birth, marriage, and death rites of the Chinese, followed by the indefatigable Mrs. Murray-Aynsley's account of secular and religious dances in Asia and Africa, which extends over both numbers, and in Part 3 is succeeded by Mr. Clouston's two Pacific folk-tales. Folk-lore amongst the Somali tribes follows that of British Guiana, and is succeeded by Cornish, Irish, Malay, and North Friesland tales. Dr. Gaster's paper, in the same part, on the modern origin of fairy-tales, is a very suggestive one. Its conclusion, after an examination of certain examples, which "can be infinitely multiplied," is "that the literature of romance and novel, be it a religious romance or one of chivalry, has passed nowadays to a great extent into the literature of fairy-tales, and that, far from being the basis, the fairy-tales are the top of the pyramid formed by the lore of the people. They are the outcome of a long *literary* influence, as well as an oral one, which was exercised upon the mind and soul of the people during centuries." What may be called the editorial matter—the notes, news, &c.—is of the usual varied and interesting character.

Sir D. Salomon's little work on accumulators, issued by Messrs. Whittaker and Co., has passed rapidly through two editions. A third and much improved edition, with many illustrations in the text, will be ready shortly.

We have received the first instalment of what promises to be an important book, "Die Elektricität des Himmels und der Erde," by Dr. Alfred Ritter von Urbanitzky. The complete work will contain about 400 illustrations, including several coloured plates. The publisher is A. Hartleben, Vienna.

We have received the first number of the *American Journal of Psychology*, edited by Prof. G. S. Hall. The object of this periodical, as the editor explains, is to record psychological work of a scientific, as distinct from a speculative, character. The present number contains, besides reviews and notes, articles on the following subjects: the variations of the normal knee-jerk and their relation to the activity of the central nervous system, by Dr. W. P. Lombard; dermal sensitiveness to gradual pressure-changes, by Prof. G. S. Hall and Mr. Y. Motoro; a method for the experimental determination of the horopter, by Christine Ladd-Franklin; and the psycho-physic law and star magnitudes, by Dr. J. Jastrow.

Six Bulletins of the United States Geological Survey, Nos. 34–39, have been sent to us. The subjects are: on the relation of the Laramie Molluscan fauna to that of the succeeding fresh-water Eocene and other groups, by Dr. C. A. White; physical properties of the iron-carburets, by Mr. C. Barus and Mr. V. Strouhal; the subsidence of fine solid particles in liquids, by Mr. C. Barus; types of the Laramie flora, by Mr. L. F. Ward; peridotite of Elliott County, Kentucky, by Mr. J. S. Diller; and the upper beaches and deltas of the glacial Lake Agassiz, by Mr. W. Upham.

In a paper which has just been reprinted from the Transactions of the New York Academy of Sciences, Mr. J. S. Newberry maintains that the decorative ideas expressed in the monuments of the ancient inhabitants of Central America have a close resemblance to the carvings executed by the Indians of the north-western coast of America, and by the people of the Pacific Islands. "Hence," says Mr. Newberry, "I am inclined to believe, as has been suggested by Baldwin, that the seeds of this ancient civilization were brought from the East Indian Archipelago from island to island across the Pacific, and that finally reaching our continent, and prevented by the great and

continuous chain of the Cordilleras from further eastward migration, it slowly spread southward to Chili, and northward to our western territories."

FIVE years ago the increase of wolves in France had become so serious that the Government found it necessary to raise the awards for killing them. In 1882, 423 wolves were killed; in 1883, 1316; in 1884, 1035; in 1885, 900; and in 1886, 760. The awards are now 200 francs for the killing of a wolf which has attacked human beings; 150 francs for one in young; 100 francs for a male wolf, and 40 francs for a cub.

IN the current number (vol. i. No. 4) of the Journal of the Pekin Oriental Society, the well-known scholar Dr. Edkins writes on local value in Chinese arithmetical notation. The principle of local value is used in Chinese commerce, strokes being used instead of special symbols for 1, 2, 3, &c., the relation of the strokes to each other showing the value of the symbol. The abacus, with its upright strings and balls, is only a help to calculation, and does not contain any new principle. Dr. Edkins describes calculating slips which have been in use in China from the most ancient times. It is curious to notice that the principle of local value adopted by the Chinese was from left to right as with ourselves. The slips here mentioned, in which local value played an important part, had been in use fourteen centuries and probably more, when in the fourteenth century the abacus was introduced. Dr. Edkins assigns the origin of the principle of local value to the Babylonians, for several reasons. The first Chinese example known to us is dated B.C. 542, while in the sixteenth century B.C. the Babylonians could extract the cube and square roots of numbers: the Hindoos do not seem to have been proficients in mathematics at so early a date as B.C. 542; so that the probability is the principle of local value in arithmetical notation found its way to China through the Phœnician traders. The Chinese, in fact, acquired it where they acquired a knowledge of the clepsydra, the dial, astronomy, and astrology.

THE creation of provincial museums in Eastern Siberia is progressing very favourably. The example given by the Minusinsk Museum has been followed at Yeniseisk, and will be followed at several other towns. The Minusinsk Museum has now 4000 speeimens of plants, 2000 of animals, and 1500 of minerals. The anthropological department has numerous models of huts and houses of the Russian and native population. The archæological collection is especially interesting; it contains 218 implements of the Stone Age, 1260 of the Bronze Age, and 1850 of the Iron Age. There is, moreover, a collection of implements used in, and produced by, local domestic trades. The whole is described in a good catalogue. Last year the Museum was visited by 8000 persons.

TWO bones which were found some time ago at Pitchery Creek, Central Queensland, attracted the attention of several persons interested in science. They were lately exhibited at a meeting of the Royal Society of New South Wales, and Mr. Etheridge explained that they were portions of the vertebral column of an extinct reptile, *Plesiosaurus*. From the transverse elongation of the portions preserved, the bones partook more of the facies of the Plesiosauri of the Cretaceous group than of those found in the Lower Mesozoic deposits.

DR. SCHWERIN, who was despatched last year by the Swedish Government to the Congo, in order to ascertain whether that place was suitable for the establishment of a Swedish colony, and to make scientific researches, has returned to Sweden with good results. He also reports having made an interesting discovery at the mouth of the river, viz. the marble pillar or *padro* erected here by Diego Cam in 1484, the first Portuguese traveller who reached the Congo. The Portuguese were in the habit of raising such *padroes*, bearing the arms of Portugal, in prominent places on the West Coast of Africa, when taking possession of territory, and it was known that one had been erected by Cam at the mouth of the Congo, but it was believed that it had been destroyed. However, Dr. Schwerin, having worked out a theory of his own, searched for this ancient monument some 6 miles further inland than the position indicated on English charts, viz. Point Padro, and here he found it. Dr. Schwerin is preparing an exhaustive account of his work on the Congo, at the expense of the Swedish Government.

AN electric railway for the dinner-table is one of the recent achievements of French ingenuity (*La Nature*, October 29). It makes the presence of servants unnecessary. The train, which runs on a line along either side of the table before the diners, consists of a platform pivoted on two bogies, one of which carries the motor, while the other is merely a supporting truck. The expenditure of electric energy is but slight, and the train is said to be thoroughly under control of the host.

THERE has been much speculation as to how the ancient Egyptians managed to erect their enormous monoliths, sometimes 100 feet in height and weighing hundreds of tons. An interesting recent article in the *Revue Scientifique*, by M. Arnaudeau, offers the explanation that water was employed. Round the obelisk, lying horizontally, with the base towards the pedestal, was raised a circular inclosure, of height equal to that of the monolith. This latter had pieces of wood, or other floats, fitted to it, especially at the upper part; so that when water was brought into the inclosure, the obelisk rose gradually to the vertical. The process may be simply imitated by introducing the end of a screw nail into a piece of cork, putting it in a basin, and then introducing water.

THE pulverizing of minerals for analysis often consumes much time, requiring, as it does, great care. A mill for the purpose, constructed on the model of the wet mill in porcelain work, has been recently brought before the Berlin Chemical Society by Herr Zulkowsky (*Berichte*, October 24). The grinding-surfaces are both agate, and the circular runner, on a vertical axis, has a sector cut out of it, and one edge of this rounded. The mill is driven by water-power, a pressure of two to three atmospheres being sufficient.

IN a paper on colour-blindness, contributed to vol. v. Part 2, of the Proceedings of the Bristol Naturalists' Society, Prof. W. Ramsay suggests that the particular defect which causes colour-blindness may lie in the brain, not in the eye. Certain persons, he points out, are incapable of judging which of two musical tones is the higher, even when they are more than an octave apart. Yet such persons hear either tone perfectly; the defect is not one of deafness. "It must be concluded," says Prof. Ramsay, "that in such a case the brain is the defaulter. And it may equally well be the case that the inability to perceive certain colours is not due to a defect in the instrument of sight—the eye, but to the power of interpreting the impressions conveyed to the brain by the optic nerve. If this is the case, the problem is no longer a physical one: it falls among those with which the mental physiologist has to deal."

A SUPPLEMENTARY mail has just arrived from Iceland, from which we learn that in spite of the ice which has blockaded the eastern and northern shores of the island there has been a good summer and autumn inland, and the harvest has been above the average. However, on the east coast the ice did not disappear till the middle of September, and on the north coast it has not remained so long as during this summer since 1846, and even then the ice-masses were far smaller than this year. In spite of this the weather has been unusually warm inland. Dr. Th. Thoroddsen, the well-known Iceland explorer, has been travelling in the north-western peninsula this year. The fisheries have entirely

failed this autumn on the north and east coast, on account of the drift-ice, but they have been good on the south coast.

THE additions to the Zoological Society's Gardens during the past week include a Mongoz Lemur (*Lemur mongoz* ♂), an Olive-gray Lemur (*Hapalemur olivaceus*) from Madagascar, presented by Capt. J. Bonnerville; an Anubis Baboon (*Cynocephalus anubis*); an Angolan Vulture (*Gypohierax angolensis*) from West Africa, presented by Capt. Augustus Kent; a Peregrine Falcon (*Falco peregrinus*), European, presented by Mr. J. G. Keulemans; a —— Scops Owl (*Scops* ——) from Baltcitan, Himalayas, presented by Mr. John H. Leech, F.Z.S.; two Rough-scaled Zonures (*Zonurus cordylus*) from Robben Island, South Africa, presented by Mr. W. K. Sibley.

OUR ASTRONOMICAL COLUMN.

THE ASTRONOMICAL SOCIETY OF FRANCE.—The science of astronomy has become so increasingly popular in France within the last few years, and Frenchmen have done so much to aid its progress that there is ground for wonder that hitherto there has been no Society in France explicitly devoted to its interests. Such a Society, on lines very similar to those of our own Royal Astronomical Society, has at length been founded, and its first meeting was held on October 12, M. Camille Flammarion, the President, being in the chair. MM. Paul and Prosper Henry, General Parmentier, and M. E. L. Trouvelot are the Vice-Presidents; and MM. Gérigny and Gunziger the Secretaries; whilst Dr. Lescarbault, M. G. Secretan, and M. Ch. Trépied are amongst the members of Council. At the first meeting, M. Trouvelot read a paper on a remarkable double shadow of the first satellite of Jupiter, observed by him in 1877 when at Cambridge, U.S.; and M. Ch. Mousette exhibited a fine photograph of a sunspot, and some large-scale photographs of portions of the solar spectrum.

THE LICK OBSERVATORY.—The *Sidereal Messenger* for the current month states that Mr. E. E. Barnard, of Nashville, Tenn., and Mr. J. M. Schaeberle, of the Ann Arbor Observatory, both well known for their cometary discoveries, have been appointed as astronomers at this Observatory.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *NOVEMBER* 20–26.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 20

Sun rises, 7h. 29m.; souths, 11h. 45m. 44·8s.; sets, 16h. 3m.: right asc. on meridian, 15h. 42·4m.; decl. 19° 42′ S. Sidereal Time at Sunset, 20h. 0m.

Moon (at First Quarter November 22, 11h.) rises, 12h. 15m.; souths, 16h. 43m.; sets, 21h. 18m.: right asc. on meridian, 20h. 41·0m.; decl. 17° 52′ S.

GEOGRAPHICAL NOTES.

THE Owen Stanley Range of New Guinea, which has been so long known at a distance, has at last been ascended. Mr. E. H. Martin, of Queensland, in August last, reached the summit of the range, which he found to be 13,205 feet high. He reports the north side of the range to be a paradise with great tree-ferns, palms, and other magnificent tropical vegetation. Mr. W. R. Cuthbertson, the leader of the Australian Geographical Society's Expedition, started for Port Moresby on July 20 last, with Mr. G. Hunter as interpreter. Mr. Cuthbertson has not yet succeeded in ascending to the highest point of the Owen Stanley Range, as he intended, but ascended Mount O'Bree, 10,240 feet.

IN No. xi. of *Petermann's Mitteilungen*, Dr. Paulitschke describes Captain Stuart King's journey into the country of the Ejssa and Gadaburssi Somali, some 70 miles to the south of Zeyla, in 1886. The paper is accompanied by a map. Dr. von Jhering and P. Langhans conclude their long and elaborate memoir on the southern colonial region of Rio Grande do Sul. Dr. Hans Schinz, who has been so long in the Lake Ngami region, criticizes severely Mr. Farini's narrative of his journey to the Kalahari Desert, the conclusion being very adverse to the trustworthiness of Mr. Farini's narrative. Perhaps the most important contribution to this number is a beautiful map of the Russo-Afghan frontier region, based upon the work of Colonel Holdich's Commission. It is remarkable that while Colonel Holdich's work is carefully locked up in the India Office as "confidential," so far as English geographers are concerned, it should be accessible to the geographers of other countries.

HERR KRAUSE has returned to the German settlement of Togo, on the Gold Coast, from his journey from Salaga through Dahomey. He has collected from 600 to 800 specimens of plants and seeds, a large number of insects, and numerous specimens of prehistoric articles found between Mosi and Timbuktu.

THE principal paper in the third part of this year's *Bulletin* of the Paris Geographical Society is an account of a journey made in 1881 by Count de Chavagnac, from Fez to Morocco, north-east to Mekenessa, and eastwards across the numerous wadis that run south into Wed Mellouja, and as far as Ajda. There is also a paper containing a good deal of useful information, and accompanied by an excellent map, on the ports of Tonquin, by M. J. Renaud. M. Datreuil de Rhins concludes his useful summary of our knowledge of Eastern Tibet.

THE session of the Royal Geographical Society began on Monday, with a paper on Siam, by Mr. J. McCarthy, Superintendent of Surveys in Siam. Mr. McCarthy has been at work for seven years on the survey of Siam, and some of the results he described in his paper, and embodied in the map by which

it was illustrated. After indicating the position of Siam in the Malay Peninsula, the author went on to say that on the west is a chain of mountains which runs in an unbroken range to Singapore, the southernmost limit of the Malay Peninsula; some of its peaks between Burmah and Siam rise to a height of 7000 feet, while one peak in the Malay Peninsula reaches 8000 feet. On the east there is another range of mountains which forms the grand watershed of all the rivers that flow into the Gulf of Tonquin and Chinese Sea on the one hand, and the Meinam Kong on the other. There are peaks in this range that reach even 9000 feet above mean sea-level. Besides these ranges there is another which breaks away from the western range from a point north-east of Chingmai, and forms the watershed between the Meinam and Meinam Kong valleys. In this range, at the source of the eastern branch of the Meinam, are famous salt-wells. The salt is procured at depths varying from 35–45 feet—in these land-locked countries as valuable as money. The greater part of the valley of the Meinam Kong and the Meinam is flat, diversified by isolated hills, and broken and jagged ridges of limestone mountains. The most important river, though not the largest, is the Meinam Chau Phraya. It is the Nile of Siam, a good rice harvest very much depending on whether the river overflows its banks or not. The eastern branch of the river is specially known for the numerous crocodiles which yearly carry off some victims. Two other rivers converge towards the Meinam, the Mei Klong and Bang Pla-Kong. All these rivers are connected by canals, rendering communication easier in a country where roads are conspicuous by their absence. The Meinam Kong is the largest river, and flows through the northern and eastern parts of the kingdom, receiving the waters of many large affluents; but the channel of this mighty river is so blocked with large rocks and cataracts, that its navigation is very difficult, and in some parts impossible even for native craft. Mr. McCarthy then went on to describe some of his journeys in detail, especially the one to the north-east frontier, which led him through scenes of surpassing beauty, and during which he opened up much new ground.

THE Arctic land seen by Sannikof eighty years ago has been seen again by the Expedition of MM. Bunge and Toll from the northern extremity of the Kotelnyi Island. The Great and Small Liakhov Islands, the Thadeus Island, and New Siberia have also been visited by the Expedition, which has returned with rich zoological, botanical, and geological collections. Throughout the summer of 1886 the ice on the Siberian coast did not move from the shores, and the hunters said that the sea had not been clear from ice since the *Vega* Expedition.

METEOROLOGICAL NOTES.

WE have lately been subjected to a series of storms which fortunately in the British Islands is not of very common occurrence. The storm of October 30, which was noticed in NATURE a few days after its occurrence, had scarcely left our shores before a fresh disturbance was approaching us from off the Atlantic, and by the evening of Monday, the 31st, another gale was blowing in Ireland, and during the night this storm extended to all parts of the British Islands. The central area of low barometer readings, which primarily occasioned the renewal of disturbed weather, kept to the westward of our coasts, but the Daily Weather Chart of November 1 shows that two secondary disturbances had been formed, one having its centre in the St. George's Channel, and the other over the Bay of Biscay. The very severe gale experienced in the south-west and west of England on November 1 was due to the former of these, the storm area passing during the day slowly up the Irish Sea. The fall of the barometer for this gale amounted to 1·02 in. at Pembroke in fourteen hours, from 6 p.m. 31st to 8 a.m. 1st; and at Lyme Regis the wind attained the velocity of 83 miles an hour between 7 and 8 o'clock in the morning. Another disturbance skirted to the westward of Ireland on the evening of the 2nd, and during the following day, causing southerly gales in many parts of the country, the barometer standing below 29 inches over the whole of the United Kingdom. On the evening of the 3rd another subsidiary was formed in the Irish Sea, and subsequently passed over the north of England, causing gales and disturbed weather in parts adjacent to its path. Before the expiration of the week a fresh disturbance was shown in the west, and on Saturday, the 5th, the barometer was again falling: the force of the wind, however, was not severe, although it blew a fresh gale in places. It will be seen from this notice that no fewer than five distinct storms were experienced in seven days, and in each case the wind was accompanied by heavy rain.

THE Meteorological Council have published Part I. of the "Hourly Readings" for 1885 (January to March) made at their self-recording observatories, together with the daily means, daily maxima and minima, and the daily range for pressure and temperature. Hourly values have now been issued in either lithographed or printed form since 1874, and afford valuable data for discussion in various ways, although the hourly means are not calculated. Corrections are given for reducing the barometric observations to mean sea-level. In connection with these observations it may be mentioned that the Meteorological Institute of the Netherlands lately published an interesting paper by M. Schokker on atmospheric disturbances studied by means of the hourly readings issued by the Meteorological Office and elsewhere; he traced on charts the positions of depressions for various hours, and showed that many phenomena which are clearly traceable from hourly observations are entirely lost sigh of on charts giving only one or two hours a day. He also quoted instances where timely warning of storms could have been given, which were not possible from the usual observations received by telegraph.

THE Hydrographic Office of the United States calls special attention to a new form for reports of storms, fog, ice, and derelicts, issued for the use of trans-Atlantic steamers. This form replaces those hitherto issued by that Office and the Signal Service, and the information thus collected is immediately utilized in preparing the telegrams sent daily to France by the United States Signal Service for the benefit of westward-bound vessels. Captains of trans-Atlantic steamships are requested, in the interest of navigation, to send in prompt and complete reports. No doubt British ship-owners will instruct their officers to co-operate in this enterprising experiment, as this country has at least equa interest with others in the safety of Atlantic navigation.

A DISCUSSION on the distribution of cloud over the eastern part of the North Atlantic, by Dr. W. Köppen, will be found in the *Annalen der Hydrographie und Maritimen Meteorologie* for October. The author points out that the cloud-conditions over the Atlantic are now fairly well known from the publications of the Meteorological Office (Captain Toynbee's great work for nine 10° squares), and the six 10° squares discussed by the Deutsche Seewarte. Dr. Köppen gives a table showing the mean monthly cloud from 20°–50° N. and from 10°–40° W., and the number of observations used, for every 5°, showing that, with regard to longitude, in the months January to April the cloud decreases north of 10° N. as we approach the shores of Africa and Europe, while in the other months this does not hold good. South of the equatorial calm-belt, May has the least cloud towards the east of the district, and in the months September to February the least cloud is towards the west. The differences of the amount of cloud with regard to latitude are much more decided, and these changes are shown on a map of equal lines of mean cloud, on the same plan as was adopted by the author in his discussion of the rainfall (NATURE, vol. xxxvi. p. 617). He also compares the cloud and rainfall curves for the yearly period, and draws attention to their marked difference in the zone of 15°–27° N. lat. While the tropical summer rains cease between 15° and 20° N., the summer maximum of cloud extends as far as 25° N. In the same way the winter maximum of cloud only extends southwards to 25° N., while the rain extends to 17° N. In these latitudes the minimum of cloud falls in the autumn, and the minimum of rain in spring. Only from 15°–17° to the southwards is the amount of cloud in spring less than in autumn, while northwards of 27° N. both minima coincide in the late summer season. Between 15° and 20° N. the end of the long dry season, lasting from February to June, is very cloudy. The author also compares his cloud-results with those obtained by M. Teisserenc de Bort from independent data (NATURE, vol. xxxvi. p. 15), and on the whole expresses himself satisfied at the agreement between the two investigations.

WE have the pleasure of recording the commencement of the publication of meteorological observations in the *Boletin de Estadistica* of Puebla (Mexico). Observations taken three times a day are published for several stations, and monthly means for several others. The stations are generally at great altitudes above the sea.

PART 2, vol. iv. of the Indian Meteorological Memoirs contains a very lucid discussion of the disastrous storm which visited Orissa in September 1885, and whose centre was at False Point on the 22nd, drawn up by Prof. A. Pedler. This storm is of considerable meteorological interest from several points of view: viz. the rapidity of its formation; its smallness, the diameter at the part of greatest wind-force being only from 100 to 200 miles; its enormous fierceness; particularly as it approached the land; and the decided indraught towards the centre as opposed to the circular theory; the extraordinary low reading of the barometer, 27·135 inches, being recorded at False Point at 6h. 30m. a.m. of the 22nd. The reading at 8h. p.m. of the 21st was 29·622 inches, thus giving a fall of 2·487 inches in 10½ hours. This is the lowest pressure ever recorded in a storm in the Bay of Bengal, and in fact is the lowest on record for any part of the world.

THE Journal of the Scottish Meteorological Society for the year 1886 contains a large amount of useful information, and testifies to increased activity, both observational and experimental. Among the various papers, all of which are of the highest importance, may be specially mentioned, (1) an address by the Hon. R. Abercromby on the modern developments of cloud knowledge (see NATURE, vol. xxxv. p. 575); (2) discussions on the winds and rainfall of Ben Nevis, and on a peculiarity of the cyclonic winds of the mountain, which has an important bearing upon weather forecasting, viz. the outflow of the wind from the cyclone when the centre is north or east of Ben Nevis towards an anticyclone or area of high pressure somewhere in an opposite direction. The prevalent wind on the Ben is north, while south-east and west-south-west are secondary points of maxima. Compared with the winds of other stations in the north of Scotland and Ireland, the wind curve is quite different. The year divides about equally into cyclonic and non-cyclonic periods. The most frequent cyclonic wind is south-west; next to this comes north, apparently due to the cyclones passing to the north of Ben Nevis. The relative frequency of the winds in non-cyclonic periods is quite different: while north still retains its place as a maximum point, the most frequent wind is south-east. In the curve for the whole year tha west-south-west winds are chiefly due to cyclonic winds, south-east to non-cyclonic, and north to both systems. In both systems the north-west wind is wettest while it blows, and the east is driest. The south-east winds, which are generally west at low levels, are the driest on Ben Nevis, with the exception of the east winds. The total amount of precipitation for the year was nearly 108 inches; the wettest month was November, 14·6 inches; and the driest February, 2·8 inches. The journal also contains an interesting account of the biological work of the Scottish Marine Station, and the results of observations at the Northern Lighthouse Station, at the stations connected with the Medical Department, including observations in Iceland, Faroe, and Uruguay, and at fifty-five stations established by the Scottish Meteorological Society, and well distributed over the country.

GEMS AND ORNAMENTAL STONES OF THE UNITED STATES.

ON Saturday, October 22, an evening lecture on this subject was delivered by Dr. A. E. Foote, of Philadelphia, in the Trophy Hall of the American Exhibition. The speaker was introduced by Mr. F. W. Rudler, the President of the Geologists' Association.

Dr. Foote remarked that hitherto mining for gems in the United States had been of a very desultory character, being principally carried on in connection with mica and other mines. The emerald and Hiddenite mines of North Carolina and the tourmaline mines of Maine are the only ones which have been worked systematically. The gems peculiar to America are *chlorastrolite*, *zonochlorite*, and *Hiddenite*. Chlorastrolite, or green star-stone, was discovered by Prof. J. D. Whitney, of the United States Geological Survey, about forty years ago. The only place where it is found is Isle Royale, Lake Superior. The island, belonging to the State of Michigan, forty miles long and five miles wide, and about twenty miles from the mainland, is composed of amygdaloidal trap, in the almond-shaped cavities of which the gem principally occurs. This green stone has a radiating structure, and shows a beautiful *chatoyance* similar to cat's-eye and other fibrous minerals.

Zonochlorite is a green-banded stone, similar to chlorastrolite in composition, discovered by Dr. Foote at Neepigon Bay on the north shore of Lake Superior. The full description was published in the Transactions of the American Association for the Advancement of Science in 1872. Its hardness is about 7; it takes a very high polish, and if it could be found in sufficient quantities would undoubtedly be extensively used.

Hiddenite is a green variety of the well-known species spodumene. A yellow variety from Brazil has been cut as a gem for many years. The green variety has been known for about seven years, and is fully as beautiful, and valued as highly, as the diamond. It occurs in connection with emeralds in North Carolina. Of *gold quartz* about £28,000 worth is sold annually. Most of this comes from California, where it is not only used as a gem, but in the manufacture of various ornaments.

Although the flexible sandstone, the reputed gangue of the diamond in Brazil, is found in mountain masses in North Carolina and other States, no very large diamonds have as yet been discovered. Many small ones are recorded from California, North Carolina, Virginia, and elsewhere. The largest was found at Manchester, near Richmond, Virginia, and weighed 23¾ carats in the rough and 11$\frac{11}{16}$ carats cut. Prof. Whitney states that the largest found in California was 7¼ carats. Rubies and sapphires have been found in the rock in the corundum mines of North Carolina, and Mr. C. S. Bement has an uncut green one in his collection that would give 80 to 100 carats' worth of good stones, one of which would probably weigh 20 carats. The largest red and blue crystal weighs 312 pounds, and belongs to Amherst College. The best sapphires are found in the placer mines of Montana. Asteriated corundums are found in Pennsylvania and elsewhere.

About £2200 worth of quartz or rock crystal is mined annually. The best localities are Hot Springs (Arkansas), North Carolina, New York, and Virginia. A portion of a mass that must have weighed over 40 pounds was recently received from Alaska, that cut a hand-glass 3 inches by 5. Rock crystal is frequently dug up in the prehistoric mounds, and was used by the medicine-men and others for telling future events. Amethysts are found in very fine specimens in Pennsylvania, Georgia, Texas, and the Lake Superior region. From the latter region they are very remarkably lined, some specimens showing "phantom crystals" equal to the Hungarian. Near the Yellowstone National Park and in the chalcedony forests of Arizona are tree-trunks, some of which are 100 feet long, mineralized by the action of silicated waters. Some of these trees are still standing upright, others, having fallen, bridge deep chasms. The once hollow cavities of some are lined with amethyst, others with agate. The Arizona agatized or jasperized wood shows the most beautiful variety of colours of any petrified wood in the world. Probably the most remarkable locality anywhere for smoky quartz, or cairngorm stone, is Pike's Peak, Colorado. Here it is found in a graphic granite associated with Amazon stone, which also makes a very beautiful green ornamental stone. The rutilated quartz, or Cupid's arrows, is found in remarkably fine specimens in North Carolina. Perhaps the most remarkable mass is one 7 inches by 3½, now in the collection of the Academy of Natural Sciences of Philadelphia. The crystals of rutile are about the size of knitting-needles. Some of the North Carolina rutile has been cut, furnishing brilliant gems, closely resembling carbonado. The rutile, geniculated till it forms a perfect circle or rosette, from Magnet Cove, Arkansas, is often mounted and worn as a gem. While opals are found at many places in the United States, they do not rival those of Queretaro in Mexico. Here are found not only the "milky opals that gleam like sullen fires in a pallid mist," but fire opals and almost every other variety known. Rhodonite, in specimens suitable for polishing, is found in Massachusetts and New Jersey. At the latter locality were obtained the finest crystals ever seen. The garnets from New Mexico and Arizona are superior to the "Cape rubies" from South Africa; and from Alaska the most beautiful crystals ever seen, in a setting of gray mica schist, have recently been obtained.

The New Mexican turquoise is mined to the value of about £700 annually. It has recently been described very fully by Prof. Clarke, Curator of the Mineralogical Department of the National Museum, and is especially interesting as being the material from which the "chalchihuitls," or most sacred images of the Aztecs, were made. The Indians still regard it as a lucky stone.

Labradorite, lately so popular for gems and ornamental stones, is found in many localities. The tourmalines of Maine are

probably the finest in the world. Here are found the Oriental sapphire, ruby, and emerald, in perfection.

Topaz has recently been found at Pike's Peak, Colorado, in large quantity. Some masses weighed 2 pounds each; and very fine clear white stones have been cut, weighing from 125 to 193 carats.

Among ornamental stones should be mentioned a very beautiful variety of serpentine from Maryland, called verd antique, which is being largely used in the interior decorations of the Philadelphia Court House. Another variety, resembling jade, is the green williamsite from Pennsylvania. Alabaster of various colours abounds in many localities; and marbles, some as beautiful as the Mexican onyx, are found in nearly every State. The malachite and azurite, jet, and many other gems of minor importance were briefly described.

THE OCTOBER METEOR-SHOWER OF 1887.

THE display of Orionids has been recently observed at this station with greater success than has attended my efforts in any previous year. This shower has not, perhaps, exhibited such richness as it did in 1877, but the present occasion has been more favourable as regards the conditions; the moon being absent from the morning sky, and a period of tolerably clear weather occurring just at the important time.

In all, I numbered ninety Orionids between October 11 and 24, and the radiant-point during this period exhibited a stationary position amongst the stars. The shower has this year met with rather a formidable rival in a bright display of forty-five meteors from a radiant at 40° + 20° close to ε Arietis. I have witnessed the latter stream in several preceding years, though not in such conspicuous strength, and have particularly referred to it in the *Monthly Notices*, vol. xliv., pp. 24–26, as furnishing many bright fireballs at this season.

It will be convenient to arrange my new observations in a tabular form:—

Date 1887 Oct.	Period of Observation. h. h.	Real Duration.	Meteors seen.	Orionids.	Arietids.	Radiant of Orionids.
11	7½ to 12½	4½	30	1	2	91° + 17°
12	8½ ,, 12½	4	31	2	1	
13	10 ,, 12	2	16	1	1	
14	9½ ,, 16¾	7	75	1	10	
15	7 ,, 8½; 10½ ,, 17	7½	86	17	7	91° + 16°
17	8 ,, 12½	4½	29	3	3	90° + 15°
19	13 ,, 15	1½	19	10	—	90½° + 15½°
20	10 ,, 15½	5¼	61	22	9	90° + 14½°
21	9 ,, 16	6¼	76	23	7	92° + 14°
23	12½ ,, 14	1½	13	1	3	— —
24	12 ,, 14½	2¼	23	9	2	91° + 16°
11 nights		46¼	459	90	45	91° + 15°

The 16th and 22nd were overcast, and on the 19th and 23rd the observations were much obstructed by clouds. It is noteworthy that I only recorded one Orionid on October 14 during a watch of seven hours, though on the following night this shower supplied seventeen meteors.

The radiant-point of the October meteors has long been accurately known. Prof. A. S. Herschel observed it with great precision on October 18, 1864, and October 20, 1865, and found the centre at 90° + 16°, and 90° + 15° respectively, in those years. All the best of later determinations have agreed closely with these results, and it will be noticed that my value for the present year, as given above, is nearly identical with them. In further confirmation I may mention that Mr. David Booth, of Leeds, observed more than sixty shooting-stars during a watch of five hours, from 10½h. to 15½h. on the night of October 20 last, and saw twenty-four Orionids which gave a sharply-defined radiant at 90° + 16°.

One of the principal objects of my late observations was to ascertain whether the radiant centre of this stream showed any displacement of position on successive nights, and similar to that affecting the Perseids of August—a peculiarity which I first pointed out in NATURE, vol. xvi. p. 362. But the radiant of the Orionids has (when the small, unavoidable errors of observation are allowed for) quite failed to exhibit any change of place relatively to the contiguous stars. It appeared to maintain an absolutely persistent position 1° north of the star ξ Orionis. My observation on October 15 placed it at 91° + 16°, and nine nights later, viz. on October 24, I found the meteors were radiating from exactly the same focus. In 1877 and 1879, October 15, I derived the radiant at 92° + 15° and 93° + 17°, and in 1878, October 22, I fixed it at 92° + 14°. A comparison of all these values renders it sufficiently obvious that there is no visible displacement in the position of the Orionid radiant during its active display from October 11 to October 24. And there is a high degree of probability that the point is stationary during the whole period of the shower's sustenance from about October 9 to October 29; but I have never secured many paths and been enabled to get a good radiant near the limiting epochs of its display, when it is extremely feeble.

Mr. Booth, at Leeds, has been carefully observing numbers of meteors during the past few months, and a searching comparison of his results with those obtained at Bristol during the progress of the Orionid shower has shown that several of the same meteors were observed at both stations. Three of these are typical members of the October display, whilst three others had their origin in the minor systems which are so plentifully distributed over the sky at this season of the year. The computed heights and paths of these six meteors are:—

Date 1887 Oct.	Hour G.M.T. h. m.	Mag.	Height at appearance.	Height at disappearance.	Length of real path.	Radiant point. ° °	Inclination to horizon. °
13	10 25	1–2	69	·50	26	73+61	48
13	11 25	2–4	70	42	37	127+83	49
[14	12 5½	4–5	64	40	26	355+36	67½
15	14 48½	1½–3	89	61	39	87+15	46
20	11 45	4–4	106	[90	34	87+21	28½
20	12 55	1–1½	92	53	70½	87+13½	33½

The three last in the list were Orionids, and they appear to have been observed at somewhat greater elevations in the atmosphere than is usual. The 4th magnitude meteor of October 20, 11h. 45m., was no less than 106 miles high at its first appearance, over a point near Eversham, Kent, and the two observations are in perfect agreement in indicating these figures. The mean of the three Orionids gives 96 miles for the beginning points and 68 for the ending, and the average radiant comes out at 87° + 16°, which is 3° or 4° west of the usual position. But the average values deduced from so small a number of instances cannot have much weight as indicating accurately either the heights or radiant of the general body of the meteors forming this notable group.

The Arietids, which have developed into an important shower this year, traverse their paths with medium speed, and are rather conspicuous meteors, without trains or streaks except in exceptional cases. As to the Orionids, they move swiftly, and are accompanied in almost every instance with streaks. The latter will sometimes brighten up considerably after the nuclei of the meteors have died away. The more brilliant Orionids are fine flashing meteors, leaving streaks which are occasionally very durable.

The contemporary showers of the October epoch, though extremely abundant, are not marked by special activity, except perhaps in the case of the Arietids, already referred to. This year the following have been the best of the minor streams:—

Date.	Radiant. ° °	Meteors.	Appearance.
October 14–15	25+44	10	Slow, faint.
,, 14–21	54+71	12	Swift.
,, 14–21	105+22	12	Very swift, streaks.
,, 20–21	125+43	7	Very swift, streaks
,, 14–23	135+68	11	Swift.
,, 12–20	312+77	8	Swift.

Of these the most pronounced is at 105° + 22°, near δ Geminorum, which I also observed in 1877 and 1879. It has also been recorded as a prominent stream by Zezioli and others, and is identical with the Gemellids of Mr. Greg's catalogue (1876). It is chiefly a morning shower; its meteors are often brilliant, and regularly display the phosphorescent streaks which form so characteristic a feature of the Perseids, Orionids, and Leonids. The shower in the head of Ursa Major at 135° + 68° is also an active one at this epoch; I saw it in 1877 at 133° + 68°, October 2–19, and these appear to be the only two observations of it obtained hitherto.

W. F. DENNING.

ON SOME OF THE AFFINITIES BETWEEN THE GANOIDEI CHONDROSTEI AND OTHER FISHES.

THE group of Ganoidei Chondrostei has hitherto been regarded as one developed during the latest period of the history of the earth. Its structure is so different from that of other classes of fish that its relationship with them cannot be easily detected. The zootomic and embryological works of the last ten years, and especially the works of Zalensky in Odessa, Parker in London, Davidoff in Munich, and van der Wighe in Holland, have brought together many important facts as to the organization and development of these interesting animals, but the information provided by these writers is either fragmentary or not full enough, and long study and labour will be required before it can be satisfactorily summed up and completed.

During the last two years I have studied the anatomy of *Acipenser ruthenus*, the commonest representative of the Acipenseridæ to be found here; and although my work is far from being completed I may beg the reader's attention to some interesting facts, which must, I think, be taken into consideration by those who try to settle the question as to the relationship of the Ganoidei Chondrostei to this or to that group of fishes.

We may begin with the teeth of these fishes, as an indication of great value, which served to distinguish this group from other Ganoidei. Teeth have been found in *Polyodon folium*, a member of the Ganoidei Chondrostei, inhabiting the rivers of North America; it has been thought that they might also be found in *Psephurus gladius* of the River Yang-tse-kiang, in China; and Prof. Zalensky has found them in *Acipenser ruthenus*, at the age of from three weeks to three months. I have had the good fortune to find teeth in almost all the Ganoidei Chondrostei of the different ages that I have examined, but they were palatine teeth, not mandibular or maxillary teeth. I have discovered and studied the palatine teeth in a two-months-old sterlet; in an *Acipenser stellatus* of from seven to eight months old; in a *Scaphirhynchus kaufmannii* from Amu-Daria of a year old; in a grown *Scaphirhynchus fedschenkoi* from Sir-Daria; and in full-grown *Polyodon folium*.

The relationship of the dimensions of the snout of fish to the age at which teeth can be found is very interesting. The long and flat snouted *Acipenser stellatus* has teeth to a more advanced age than the short and narrow snouted sterlet; the teeth of a wide-snouted Scaphirhynchus not attaining a good development but are preserved until maturity; the spade-snouted Polyodon preserves its teeth during the whole of its life. In all the other representatives of Acipenser and Scaphirhynchus can be found at any stage traces of palatine teeth in the shape of two similar prominences, which, by their structure, can be distinguished from the surrounding parts of the mouth.

This dependence of a long preservation of teeth on the development of the snout of Ganoidei Chondrostei, together with the geographical distribution of these fish, shows the greater antiquity of the tooth-preserving kinds of Scaphirhynchus and Polyodon, than of the Acipenser. Species of one kind, inhabiting such widely separated water-reservoirs as the Aral Sea and Mississippi, or the Yang-tse-kiang and the continental rivers of North America, must be representatives of very old forms, remains of former fauna; their having, at a mature age, organs that do not serve them, but which merely remain as an inheritance from former periods, is a confirmation of their supposed antiquity—a conclusion drawn from zoogeographical observations.

The structure and development of the dorsal shields, which, in the case of Acipenseridæ, spread all along the dorsal surface, from the back edge of the head down to the dorsal fins, may also, I think, help us to discern affinities between Ganoidei Chondrostei and other fish. The first to pay attention to these shields, and to suppose they were an embryonal dorsal fin, was Prof. Zalensky. About the same time Prof. Goethe described a similar fin of a six-weeks-old sterlet, hinting, by the way, that the dorsal shields might be compared with the dorsal rays of a fossil fish, Cœlacanthus. I have succeeded in investigating the dorsal shields of a two-months-old sterlet, and in making a whole series of cross sections, and I have arrived at the conclusion that Zalensky's and Goethe's suppositions are fully established by facts. Indeed, between the shields spreads a membrane, in which can be seen the same horny rays that are generally seen in developing fins of fish; right and left of each dorsal shield there is a muscle, traces of which can also be found under the shields of grown sterlets. At last, having made cross-sections of oxidized dorsal shields of grown sterlets, a canal could be perceived in them. These canals are particularly well seen in Scaphirhynchus, as an older and a better representative of the original type.

Knowing that Dr. Günther in his excellent book on ichthyology places the Acipenseridæ and Cœlacanthi next to the Polypteroidei, I availed myself of the offer of Prof. Bogdanoff, Director of the Moscow Museum, and my teacher, to let me examine the only dry specimen of *Polypterus senegalensis* that was in the Museum. Comparing the numerous small fins spreading all along the back of Polypterus, there being a great and wide front bone-ray, and the others being thin and horny, I became convinced of their complete similarity to the dorsal shields of a young sterlet and to the membranes which connect them.

In the wide bone-ray of Polypterus a ray channel could also be discerned, and the rays of the membrane that spreads behind the wide ray were also horny, like the rays of the membrane of an embryonal fin of a sterlet. This brought me to the conclusion that the ancestors of both the Acipenseridæ and the Polypteroidei had not only a back fin, but also well developed front dorsal fins, with great bone-rays and smaller horny rays, and were, perhaps, nearer to each other than their present descendants.

A study of other organs, especially those in young Acipenseridæ and Scaphirhynchus, convinces me that there is a closer relationship between the Ganoidei Chondrostei and the Polypteroidei than has hitherto been supposed. It is well known that the conus arteriosus of Acipenser is distinguished from the same organ of the Polypterus and Lepidosteus by a much smaller number of transversal rows of valves. In young sterlets I have found, besides developed valves, undeveloped folds lying between the valves. In place of such undeveloped valves, in the case of grown fish, as for example in a specimen of *Acipenser huso* which I dissected, and which was about 10 feet long, an unevenness and roughness of surface are noticed. The air-bladder, which in Lepidosteus and Polypterus partly resembles the lung of Dipnoi, when attentively studied in the Acipenseridæ does not appear to be so well adapted to its new functions. Its coatings include many ramifications of vessels, the histological structure of which is so similar to the structure of the coatings of the digestive organs that it is much easier to recognize their relative layers than in those of other fishes, where the air-bladder is fully adapted to its functions. The ductus pneumaticus, in young sterlets especially, is very wide; a two-months-old sterlet has it of almost the same width as an œsophagus, and the food of the small fish, consisting mostly of forms of Cladocera and Ostracoda, and also of statoblasts of Polyzoa, especially Alcyonella, fills the cavity of the air-bladder like the cavity of the stomach.

Though the brain of these fishes has been well investigated, yet in its organization one finds much that is interesting. For example, the cerebral hemispheres of the prosencephalon of Scaphirhynchus proved to be more similar to the hemispheres of Dipnoi and Lepidosteus and Protopterus, than to those of Acipenser. The lateral layers are turned upward, so that the upper portion of the hemispheres proved to consist, not of one pallium, as in Acipenser, but also of the coating of the cerebrum. The epiphysis cerebri, being a changeable organ, proved to vary even in the limits of the genus Acipenser. Thus, its front end in *Acipenser sturio* reached as far as the line connecting the two lower nostrils, forming an angle of nearly 28° with the surface of the brain, whereas in *Acipenser ruthenus* the epiphysis forms an angle of almost 80°, and becomes a much shorter organ. In some sterlets the end of the epiphysis cerebri went through the cranium, and was only covered by the bone shields of the exterior coating. Scaphirhynchus had the epiphysis less changeable and more similar to the epiphysis of other Ganoidei and Dipnoi. In other respects the brain of Scaphirhynchus also proved to have a closer resemblance to the other Ganoidei than to the Acipenser. Thus, its valvula cerebelli and lobi inferiores are more developed than those of a sterlet, and even remind one of the brain of Amia and its near relatives Teleostei.

Notwithstanding the scantiness of the facts stated here, I indulge the hope that they may add something to the means at our disposal for the settlement of the relationship between Ganoidei Chondrostei and other Ganoidei.

NICHOLAS ZOGRAFF.

Moscow, 20/8 September 1878.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. x. No. 1 (Baltimore: Johns Hopkins University, 1887).—The number opens with the concluding lecture (the 33rd) of Prof. Sylvester's course on the theory of reciprocants, in which is investigated the differential equation of a cubic curve having a given absolute invariant S^3/T^2. A supplemental "lecture" is supplied by the reporter (Mr. Hammond) from the lecturer's surplus material: this "constitutes probably the most difficult problem in elimination which has been effected up to the present time." All admirers of Prof. Sylvester's brilliant genius will be glad to have the fine presentment of his features which accompanies this number.—Algebraic surfaces of which every plane section is unicursal in the light of n-dimensional geometry is devoted to a proof and to illustrations, by Mr. E. H. Moore, Jun., of a theorem due to Picard, viz. "Les seules surfaces algébriques dont toutes les sections planes sont unicursales sont les surfaces réglées unicursales et la surface du quatrième degré de Steiner."—Mr. Morgan Jenkins, in a paper on Prof. Cayley's extension of Arbogast's method of derivations, presents in a simplified form results given by the elder mathematician in a memoir printed in the Phil. Trans. (read December 1860).—Properties of a complete table of symmetric functions, by Capt. P. A. Macmahon, R.A., establishes some remarkable features of a tabulation set forth by Mr. Durfee in vol. v. of the *Journal*.—Oskar Bolza, in his article on binary sextics with linear transformations into themselves, considers those binary sextics which remain unchanged (or are only changed by a constant factor) for certain linear transformations of the variables.—Prof. Cayley follows with the sequel to his memoir on the transformation of elliptic functions (vol. ix.), and Prof. Woolsey Johnson closes the number with the symbolic treatment of exact linear differential equations.

Bulletin de la Société des Naturalistes de Moscou, 1887, iii.—Comparative osteology of the penguins and its bearing upon the classification of birds, by Dr. M. Menzbier (in German; with a plate).—The Hessian fly, by Prof. K. Lindeman (in German).—Chemical composition of the Lipetsk mineral springs, by A. Kislakovsky. A series of chemical analyses has been undertaken in order to ascertain how far the composition of the springs is liable to undergo changes at different times of the year. The admixture of water flowing from sweet springs makes the amount of $FeCO_3$ to vary from 0·016 to 0·032, and from 0·008 to 0·025 in different springs.—On the increase in the number of thunderbolts and its causes, by J. Weinberg (in German).—Enumeration of the vascular plants of Caucasus, by M. Smirnoff (in French). This fourth paper of the introduction which the author has written to precede his enumeration of plants discusses the following important subjects: evaporation, limits of perennial snow in Caucasia and neighbouring highlands, the present and ancient glaciers of Caucasus, and the geology of the country since the later Tertiary. The twelve botanical regions into which the author divides Caucasia are given with short characteristics of their physical features. On the whole the paper is a most valuable contribution to the knowledge of Caucasus.—List of plants growing in the province of Tamboff, by D. Litvinoff (continued).—*Otiorhynchus turca*, Steven, an enemy of the vine-tree, by E. Ballion. It has been found at Novorosiysk, on the east coast of the Black Sea, and must have immigrated from Asia Minor and Syria.

SOCIETIES AND ACADEMIES.

London.

Mathematical Society, November 10.—Sir J. Cockle, F.R.S., President, in the chair.—Prof. Sylvester, F.R.S., being incapacitated by an accident to his leg from attending in person to receive the De Morgan Medal, awarded him by the Council in June last, deputed Mr. J. Hammond to represent him. The President, after a few remarks eulogistic of Prof. Sylvester's numerous discoveries, presented the medal to Mr. Hammond, who made a felicitous reply.—The Treasurer (A. B. Kempe, F.R.S.), after having read his Report, announced to the meeting that the Society's application to the Privy Council for the grant of a charter had failed.—The following were elected to act as the Council for the ensuing session:—President: Sir J. Cockle, F.R.S. Vice-Presidents: Dr. J. W. L. Glaisher, F.R.S., Prof. Hart, and Lord Rayleigh, Sec.R.S. Treasurer: Mr. A. B. Kempe, F.R.S. Hon. Secs.: Messrs. M. Jenkins and R. Tucker. Other Members: Messrs. A. Buchheim, E. B. Elliott, A. G. Greenhill, J. Hammond, J. Larmor, C. Leudesdorf, Captain P. A. Macmahon, R.A., S. Roberts, F.R.S., and J. J. Walker, F.R.S.—The following communications were made:—On pure ternary reciprocants and functions allied to them, by E. B. Elliott.—On the general linear differential equation of the second order, by the President.—On the stability of a liquid ellipsoid which is rotating about a principal axis under the influence of its own attraction, by A. B. Basset.—On modular equations and geometry of the quartic, by R. Russell.—The differential equations satisfied by concomitants of quantics, by A. R. Forsyth, F.R.S.—On the stability or instability of certain fluid motions (ii.), by Lord Rayleigh, Sec.R.S.—Notes on a system of three conics touching at one point, by Dr. Wolstenholme.

Geologists' Association, November 4.—Mr. F. W. Rudler, President, in the chair.—The President delivered the opening address of the session, entitled "Fifty Years' Progress in British Geology." He drew a picture of the state of geology in 1837, and contrasted it with that in 1887. The principal questions discussed were the old controversy between the Catastrophists and Uniformitarians, the development of Palæozoic geology, the origin of the Drift, and the antiquity of man. In recent years the warmest discussions have referred to the Archæan rocks and to the Glacial Drift. Attention was directed to the debt which geology owes to engineering, especially to the development of our railway system and to artesian borings. The sub-Wealden exploration was explained, and a Jubilee boring suggested. Deep-sea exploration was touched upon. Turning to petrology, its low condition in 1837 was pointed out, and its recent development traced to the introduction of microscopic methods of research. The history of palæontology was briefly sketched, special attention being called to the work of the Palæontographical Society. Improvements in the Geological Department of the British Museum were noticed, and reference was made to the history of the Geological Survey and the Museum of Practical Geology. In conclusion, it was pointed out that by a happy accident the meeting of the International Geological Congress in London next year will coincide with the centenary of the foundation of British geology—the original publication of Hutton's "Theory of the Earth" in 1788.

Chemical Society, November 3.—Mr. William Crookes, F.R.S., President, in the chair.—The following papers were read:—Note on the atomic weight of gold, by Prof. T. E. Thorpe, F.R.S., and Mr. A. P. Laurie.—The ni teraction of zinc and sulphuric acid, by Mr. M. M. Pattison Muir and Mr. R. H. Adie.—Note on safety-taps, by Mr. W. A. Shenstone.—Note on Guthrie's compound of amylene with nitrogen peroxide, by Dr. A. K. Miller.—The dehydration of metallic hydroxides by heat, with special reference to the polymerization of the oxides and to the periodic law, by Prof. Carnelley and Dr. James Walker, University College, Dundee.—The bromination of naphthalene β-sulphonic acid, by Mr. G. Stallard.—The constitution of the three isomeric pyrocresols, by Dr. W. Bott.—Preliminary note on certain products from teak, by Mr. R. Romanis.

Paris.

Academy of Sciences, November 7.—M. Janssen in the chair.—On a paradox analogous to the St. Petersburg problem, by M. J. Bertrand. The paper deals with the doctrine of probabilities, and shows that, if a gambler plays under conditions involving all but inevitable ruin, equity requires the remotely contingent prize to be infinite.—On the state of the potassa in plants, in the soil and vegetable humus, and on its quantitative analysis, by MM. Berthelot and André. These studies have been undertaken to determine how far the potassa present in plants and arable land is in the condition of salts soluble in water, or of insoluble salts capable or not of resisting the action of attenuated acids. The researches are in continuation of those already described connected with the analysis of the soluble and insoluble carbon present in the soil, and of the nitrous compounds in their various forms of nitrates, free ammonia, &c.—Inquiry into the two fundamental principles of the accepted doctrines regarding cerebral dualism in voluntary motions, by M. Brown-Séquard. In continuation of his recent communication on this subject, the author here advances facts and arguments, some of which go directly to show that each half of the encephalon may independently serve for the production of voluntary movements in both sides of the body, while others

tend to overthrow the fundamental principles of the views generally held regarding the part played by both hemispheres in producing voluntary movements. Several interesting manifestations are described, proving that the motor effects of cerebral irritations are in absolute contradiction to the current theories.—On the *Elasmotherium*, by M. Albert Gaudry. In connection with some remains of this extinct mammal recently found on the River Kinel in the government of Samara (Russia), and presented to the Academy by M. Paul Ossoskoff, some remarks are made by the author, who assigns to the *Elasmotherium* a position intermediate in size between the mammoth and *Rhinoceros tichorhinus*, his contemporaries. In his general structure he appears to have approached more nearly to the latter animal, the radius, tibia, cubitus, calcaneum, and some other bones presenting the closest resemblance to those of a gigantic rhinoceros.—On a geometric form of the effects of radiation in the diurnal motion of the stars, by M. Gruey. A number of propositions are here announced, whose further development and demonstration are reserved for a future number of the *Bulletin Astronomique*, where a full demonstration will be given of the theorem that, in a sidereal day the apparent position of a star describes a conic section round its true position.—On the internal temperature of glaciers, by MM. Ed. Hagenbach and F. A. Forel. The different temperatures determined by careful experiment in the Arolla glacier are explained by the varying pressure to which different parts of the glacier are subjected. The normal temperature below zero is shown to be the effect of pressure, which lowers the melting-point of ice, thus verifying in Nature facts already theoretically demonstrated by Sir W. Thomson and others, but hitherto studied only in the laboratory.—Remarks on the Gulf Stream, by M. J. Thoulet. Comparing his own observations made on board the *Clorinde* in 1886 with those of Mr. Buchanan during the *Challenger* Expedition, the author finds that the Gulf Stream is comparable to a river with a greater fall in its upper than in its lower reaches. A relatively steep valley separates it on the left from the United States current setting southwards from Newfoundland, while its more gently sloping right bank skirting the ocean presents a much broader expanse. Thus is explained the direction of the driftwood carried from America towards the north-west coast of Europe.—Researches on the distribution of temperature and of barometric pressure on the surface of the globe, by M. Alexis de Tillo. The author describes some general charts which he has prepared, based on the labours of M. Léon Teisserenc de Bort, and of Herr J. Hann, of Vienna, showing the mean isobars and isothermal lines for the year, and the months of January and July, for the whole world. For the general conditions of the terrestrial atmosphere he finds that, when the mean temperature $\left.\begin{matrix}\text{falls}\\ \text{rises}\end{matrix}\right\}$ within the limits of 1°·6 and 4°·7, the pressure $\left.\begin{matrix}\text{increases}\\ \text{diminishes}\end{matrix}\right\}$ to the extent of 1 millimetre.—On the metallic derivatives of acetylacetone, by M. Alphonse Combes. From the researches here described, the author concludes that this substance decomposes all the carbonates, even that of potassa; that it displaces the acetic acid of the acetate of copper, and even the hydrochloric acid; that it consequently acts as a strong acid on the metallic salts. Nothing, so far, distinguishes its action from that of a monobasic acid, although this function is clearly distinguished by certain properties of its salts from the acid function properly so called.—On the part played by the stomata in the inspiration and expiration of gases, by M. L. Mangin. From the experiments here described the author concludes generally that the stomata are indispensable for the circulation of the gases in aërial plants, the occlusion of these orifices bringing about a greater or lesser diminution in the exchanges of the respiratory gases, and a very considerable decrease in the exchanges of chlorophyllian gases.—On the invasion of *Coniothyrium diplodiella* in 1887, by MM. G. Foex and L. Ravaz. This organism, already observed in 1879 by Spegazzini in Italy, and in 1885 by Viala in the department of the Isère, has this year invaded an extensive region in the South of France. Whether it is a true parasite, or a saprophyte, or whether it assumes both of these characters according to circumstances, is a point which has not yet been decided.

Berlin.

Meteorological Society, November 1.—Prof. von Bezold, President, in the chair.—Dr. von Helmholtz discussed his most recent researches on the formation of mist under the influence of chemical processes, and laid stress at the same time upon the relation of his results to the phenomena of meteorology.—Dr. Sprung gave an account of observations made with thermometers attached to various barometers. During a comparison of the barometers from various stations with a normal barometer, the experiments being conducted in a cellar, he found that the thermometers showed considerable differences in their readings; their differences were still observed when the comparison of the barometers was made in a room at the surface of the earth, and the barometers were placed side by side in the same frame. The speaker was hence led to compare three thermometers, of which one was surrounded by a nickel-plated cylinder; the second was surrounded by a varnished cylinder, and the third had no covering at all. When placed near an open window the instrument with the nickel-plated covering registered the highest temperature, but when placed near a hot stove it recorded the lowest. The differences in reading varied at different times of the year, and amounted to several degrees. In practice these differences of the thermometer-reading can have no influence on the reading of the barometer, since it may be assumed that the mercury in the barometer has always the same temperature as that indicated by the thermometer, and that the reading of the barometer is reduced to zero.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Practical Treatise on Bridge Construction: T. Claxton Fidler (Griffin).—The Real History of the Rosicrucians: A. E. Waite (Redway).—Calendar of University College, Nottingham, 1887–88.—Totemism: J. G. Frazer (Black).—Animal Magnetism: Binet and Féré (Kegan Paul).—Living Lights: C. F. Holder (Sampson Low).—L'Homme avant l'Histoire: Ch. Debierre (Baillière).—The Flora of Howth: H. C. Hart (Hodges, Figgis, and Co.).—Lectures on Bacteria: A. De Bary; second improved edition, translated by H. E. F. Garnsey, revised by I. B. Balfour (Clarendon Press).—The Final Results of the Triangulation of the New York State Survey (Albany, N.Y.).—Catalogue of the Moths of India, part 1: Cotes and Swinhoe (Calcutta).—China in America; a Study in the Social Life of the Chinese: S. Culin (Philadelphia).—Catalog der Conchylien-Sammlung, Vierte Lief (Paetel, Berlin).—Fishery Barometer Manual: R. H. Scott (Eyre and Spottiswoode).—Folk-lore Journal, vol. v. part 4 (Stock).—Proceedings of the Royal Society of Edinburgh, No. 123.—Journal of the Royal Agricultural Society, October (Murray).—Archives Italiennes de Biologie, tome viii. fasc. iii. (Loescher, Turin).

THURSDAY, NOVEMBER 24, 1887.

CHARLES DARWIN.

The Life and Letters of Charles Darwin, including an Autobiographical Chapter. Edited by his Son, Francis Darwin. In Three Volumes. (London: John Murray, 1887.)

TO write a biography is a task which is almost a proverb for difficulty. It is no easier for a relative than for a stranger, because, if a more intimate knowledge of the details lightens the labour, affection is apt to warp the judgment, and checks perfect freedom of expression. In the biography, however, of Charles Darwin, there was no temptation to reticence, no need for firmness. His was a life, simple, noble, blameless. Still, this very simplicity and unostentatious rectitude presented their own difficulties. After the long and interesting voyage in early manhood, it was a life singularly uneventful, a life of patient labour, one long struggle against sickness. Thus its record when written might readily have been unexceptionable, but dull.

This cannot be said of the Life of Charles Darwin. It will take its place, I venture to predict, with Boswell's Life of Johnson, Lockhart's Life of Scott, Stanley's Life of Arnold, and the comparatively small number of biographies which have attained to first-class rank in literature. Mr. Francis Darwin has made excellent use of the materials at his disposal. These were considerable. They consisted of a short sketch written in his later years by Charles Darwin himself, for the information of his family, and of a large number of letters. Mr. Francis Darwin had, in addition, the special advantage of having shared in the labours of his father during the last eight years of his life.

The chapters written by the editor are of the highest interest and value, but as far as possible the story is told by Charles Darwin himself; the letters being merely strung together by occasional explanatory paragraphs, which form a connecting thread. Selection must have been no easy task, but it has been well done, and numerous as are the letters and large as is the book one almost wishes they had been more and it had been larger. Yet Darwin was hardly what most people would call a good letter-writer. His letters were often written hurriedly, and bear the marks of hasty composition; but there is not seldom a terseness of phrase, and always a vigour of expression, which makes them peculiarly attractive. These letters, too, are thoroughly characteristic of the man. They breathe the quenchless energy, the "dogged" endurance, the hidden tenderness, the sweet reasonableness, the imperturbable equanimity, of his nature; and they show, on rare occasions, that capacity for indignation without which a character so amiable might have degenerated into weakness.

The autobiographical sketch tells us the particulars of Charles Darwin's early life. Born at Shrewsbury in 1809, the son of a physician in large practice, and grandson of the well-known Dr. Erasmus Darwin, author of "Zoonomia," Charles Darwin was educated at the grammar-school of that town, under Dr. Butler, one of its most noted head masters. Neither in childhood nor in boyhood does he appear to have given promise of exceptional powers, though the taste for collecting manifested itself at a very early age, and he was obviously more thoughtful and determined to understand things thoroughly than the average boy. But the school system of education which, as usual then, was wholly classical, did nothing to bring out the special powers of his mind. Indeed, he was once even rebuked by the head master for wasting his time on such a useless subject as chemistry. He passed, in short, through Shrewsbury school as a well-conducted boy of ordinary ability, perhaps a little below the average. "A good lad, but not quick or particularly studious," would probably have been the verdict of his masters.

After leaving Shrewsbury, Darwin studied for a couple of years at the University of Edinburgh, attending medical lectures, with the idea of adopting that profession. But for the surgical side of it he already felt a disinclination; and unfortunately for him, as he relates, the dreariness of the lectures on anatomy indirectly deterred him from the practice of dissection, which would have been a useful training for his later life. He made, however, friends, who aided in developing his love for natural history, though he tells us that the dullness of the geological lectures produced in him "the determination never as long as I lived to read a book in geology, or in any way to study the science." A resolve, happily, before long rescinded.

From Edinburgh, Charles Darwin went to Cambridge. Here he entered at Christ's College, where his elder brother, Erasmus, was already a student. There was then an idea that, as he clearly had no strong taste for medicine, he should be ordained. As he says, "Considering how fiercely I have been attacked by the orthodox, it seems ludicrous that I once intended to be a clergyman." Darwin had at no time of his life any tendency to superstition, otherwise one might observe that extremes in religious opinion are not so wide apart as the remark just quoted seems to imply. At the same time he tells us that a German phrenologist had declared that he "had the bump of reverence developed enough for ten priests."

He brought little classical knowledge from Shrewsbury, and left much of that behind at Edinburgh; he had no taste for mathematics, and natural science was not then recognized in the curriculum at Cambridge. So he read little, and took an ordinary degree. Thus he doubtless appeared to be wasting his time, and accuses himself of so doing. But one can see that the groundwork was being laid for the future. He acquired friends, some of like tastes; his interest in natural history increased, and was developed by the opportunities which the district afforded, especially for collecting beetles, then the ruling passion. His health, too, at this time appears to have been good; he was an active pedestrian and a keen sportsman, enjoying society, and not without a love of music.

But the friendship of Henslow was probably the greatest boon which he owed to Cambridge. Acquaintance soon ripened into steadfast friendship, and the wider knowledge and formed habits of the older man produced, as Darwin gratefully admits, the best possible influence on the younger. Through Henslow also, shortly after Darwin had taken his degree, the offer was made to join the *Beagle* as naturalist, which may fairly be called the turning-point of his life. It is interesting to see how

evenly balanced the reasons for and against acceptance then seemed to be, and how nearly the offer was refused. He wished to go, but Dr. Darwin, his father, for various reasons—among them the fear that so long a voyage would unsettle his son for life—was opposed to the plan. Chiefly through the influence of Darwin's maternal uncle, Mr. Josiah Wedgwood, the father's objections were overcome. Capt. Fitzroy, however, who was a disciple of Lavater, was nearly refusing his services because of the shape of his nose, which was not sufficiently indicative of determination and energy! Considerable delay arose from one cause or another, but the vessel finally sailed from Plymouth on December 27, 1831.

Though Henslow was Professor of Botany, it was impossible to know him without being infected with geology; so by this time the resolution against that science had been rescinded, and Darwin had even accompanied Sedgwick on one of his journeys in North Wales. The tale of the work during the voyage of the *Beagle* has been told in the well-known volumes; but we have here a series of letters which record many incidents of the journey, and indicate the development of the writer's mental powers and the thoughts which were already beginning to quicken into life. It is amusing to read that now the new love is sometimes stronger than the old. "But geology carries the day; it is like the pleasure of gambling. Speculating on first arriving what the rocks may be, I often mentally cry out, 'Three to one Tertiary against Primitive,' but the latter have hitherto won all the bets." Later there is a conflict even in his geological preferences. "I am quite charmed with geology, but, like the wise animal between two bundles of hay, I do not know which to like the best, the old crystalline group of rocks or the softer and fossiliferous beds." But notwithstanding these mental "lovers' quarrels," notwithstanding the serious drawback of incessant suffering from sea-sickness, and one grave illness of an unknown nature, a large number of specimens and a wonderful store of observations were accumulated in almost every department of natural history, which served as the foundation for the great superstructure to which his life was devoted.

On Darwin's return to England in 1836, he oscillated for a time between Cambridge and London, working at the results of his voyage as hard as his health, now seriously impaired, permitted. In 1839 he married, and after residing in Gower Street till the autumn of 1842, moved, in the hope of benefit from country air, to a house which he purchased at Down, in Kent, and in which the remainder of his life was spent.

Here, after the immediate fruits of the *Beagle* voyage were given to the world, he began to develop the great idea of which the germ had been sown and quickened during his wanderings. One chapter describes how "the foundations of the Origin of Species were laid" between the years 1837 and 1844; another narrates its growth. In 1856, partly in consequence of Lyell's advice, the book was begun for which such long preparation had been made, and by the month of June 1858 about one-half was written. It was, however, on a much greater scale than that which has now become classic in England,—"three or four times as extensive." Then suddenly all was changed by the receipt of a manuscript from Mr. Wallace, from his distant sphere of work in the Malay Archipelago, which coincided so exactly with his own views that, as Darwin writes to Lyell, "if Wallace had my manuscript sketch written out in 1842, he could not have made a better short abstract." The story of this interesting episode, so honourable in every respect to all concerned, is told, chiefly by means of letters, in one chapter of the book. In these days, when too often the stream of scientific life is ruffled by miserable personal squabbles about priority in some trifling discovery, it is well to learn how men acted whose hearts were as large as their intellects were great.

The result of the simultaneous announcement of the hypothesis thus independently framed was that the plan of the larger work was abandoned, and the "Origin of Species by means of Natural Selection," or "An Abstract of an Essay on the Origin of Species through Natural Selection," as the author would have preferred to call it, was published in 1859. It is needless to epitomize the story of its reception by the public—of the opposition which it encountered—of the storm which it aroused—of its ultimate triumph: all this is admirably told by Prof. Huxley in a chapter which he has contributed to the work.

Of all the accusations brought against Darwin, perhaps the most unreasonable was the frequent one that he had "abandoned the true Baconian method." I do not profess to be very familiar with the philosophy of Bacon; but if accumulating a mass of facts, co-ordinating them, and then drawing inductions, is not the true method of science, I do not know of any other; and this method inspires every chapter of the "Origin of Species."

In the correspondence which was written during the remainder of the author's life, occupying nearly half the work, we read of how the "Origin of Species" won its way, edition following edition, and of the series of later works and occasional papers which continued till within a few months of the end. This came rather suddenly, though in the fullness of years. For the last ten years of his life his health had appeared somewhat better than formerly, but in the early months of 1882 it gave repeated cause for alarm, and at last, on April 19, after a brief period of suffering, he ceased from that labour which only sickness had ever made a burden.

The quantity of work which he had accomplished is astonishing when its quality—always the best that could be done by the man—is considered. True, Darwin, though only to be called wealthy towards the end of his life, was always free from the necessity of bread-winning. But then—and what a terrible set-off this implies—"for nearly forty years he never knew one day of the health of ordinary men, and thus his life was one long struggle against the weariness and strain of sickness."

In one respect Darwin was *felix opportunitate vitæ*. He lived before scientific literature had attained its present overwhelming proportions. It is charming to read such a passage as this: "Geology is a capital science to begin, as it requires nothing but a little reading, thinking, and hammering." We might add, "with the mind of a Darwin,"—at least to get such wonderful results as in the "Geological Observations." If anyone of the present day is getting proud of what he may have done in petrology, I would prescribe Part I. of that work as a corrective. But if now we learn much from others, and gain much

from the perfection of our means of research, we are apt to lose in independence and vigour of mind, to say nothing of the time which is wasted in the weary wading through piles of periodicals, often with but little fruit as the result. Mathematicians know that solving problems gives a strength to the mind which cannot be obtained from the most careful study of book-work, and I have often ventured to think that to write the section on the "literature of the subject" as the last stage of a research is not so much to "put the cart before the horse" as it seems. Something, too, may be lost through the very perfection of the means of research in natural history: the mind may be tempted to dwell too much on details; and the over-careful study of these may lead men to miss the greater principles. Darwin was an observer, precise and minute as any, but it is interesting to note that he was always guided by a selective principle.

The greatest charm of the "Life" is that it draws so vivid a picture of the man himself—partly from the unconscious self-portraiture of his letters, partly from the tender touch of his son's hand, aided by the loving memories of other members of his family. Before us rises that tall, slightly stooping form, either walking with swinging though often feeble step, cloaked and staff in hand, along the "sand walk," or seated or reclining in that study which bore silent testimony to the orderly habits learnt in the tiny cabin of the *Beagle*; we see that massive forehead, those keen yet kindly eyes, shadowed by those overhanging brows, the sparse gray hair, the long gray beard, that winning smile which lit up those rugged features; we hear once more the kindly voice; but better still, there rises, fresh and ever instructive, the memory not only of one of the grandest intellects, but also of one of the noblest and truest natures, among the sons of men. Unruffled by carping criticism and virulent abuse, in silent dignity Charles Darwin laboured on, in the quiet consciousness of strength and the conviction that truth would at last prevail. No one can read the life of Darwin without feeling as if some healthful air from a better world had braced his moral fibre and nerved him for more earnest and more unselfish work.

Truly the last scene of all was a "Great Lesson." His family would have laid him in the quiet churchyard near his own home, but his fellow-workers in science desired and obtained that his grave should be made in Westminster Abbey. Some quarter of a century before that day many thoughtful men hesitated in accepting, or even opposed, the views which he had maintained; while the camp-followers and swash-bucklers of the religious world had discharged at him their volleys of vituperation. The one had been for the most part persuaded; the other had slunk away to growl in obscurity. Now, around that grave in the Valhalla of Britain, were gathered the leaders in literature and science, men of every rank in life, of every form of creed—from the most sincere Christian to the no less sincere Agnostic. Time had shown that there was no necessary opposition between the inductions of science and those deeper aspirations and beliefs upon which we must not here touch, and men who on such points felt deeply but differently from Charles Darwin came no less willingly than others to pay the last honours to one who was not only a great philosopher but also emphatically a good man.

T. G. BONNEY.

OUR BOOK SHELF.

A Treatise on the Integral Calculus. Part I. Containing an Elementary Account of Elliptic Integrals and Applications to Plane Curves, with numerous Examples. By Ralph A. Roberts, M.A. (Dublin: Hodges, 1887.)

MOST students, on taking up this book, will be disposed to ask, "Is there any room or necessity for another work on the Calculus just now? Is not Williamson up to date?" Mr. Roberts gives no sign, and so we are led to search out for ourselves a reason for the existence of the work, and a justification of the same. In his two previous books our author makes great use of elliptic functions, and a chapter is devoted to the discussion of them in the book before us, and, further, this fact is prominently noted on the title-page; hence we conclude that Mr. Roberts has had in view mainly the treatment of these integrals, and to make his treatise self-sufficient he has surrounded this special subject with such preliminaries and accessories as he deems suitable for the elucidation of his theme. The author has produced a capital book, for he writes with extreme care, and full knowledge and command of his subject. There appears to us to be in many parts a novel treatment—*i.e.* considering the matter in the light of English treatises on the Calculus—and there is copious illustration. There is large opportunity for practice afforded by the numerous examples inserted in the body of the work, and also at the end. Many of these are not intended, or at any rate are not suitable, for babes; they are strong meat for adults. There is an index and the usual table of contents.

Solutions to Problems contained in a Treatise on Plane Co-ordinate Geometry. By I. Todhunter, F.R.S. Edited by C. W. Bourne, M.A. (London: Macmillan and Co., 1887.)

THIS is not a work brought out with a rush, for the greater portion of the solutions were drawn up by the author fifteen years ago. To students using the text-book this will be a valuable companion, for Mr. Bourne has executed his task with care and ability. Geometrical as well as analytical solutions are given, and impart a pleasant feature to the book. For Mr. Bourne's sake we regret that the foundation is giving way, as few students now read the "Conics," for that fate is befalling it which the author himself says is "the fate of all academical text-books," viz. obscurity ("W. Whewell," vol. i. p. 24). Todhunter's own views respecting "Printed Solutions" are given in his "Essays" (p. 81). The exercises, however, will retain their utility as tests for ascertaining a pupil's grasp of the subject, in spite of the decay of the setting, and the "Solutions" we can recommend to students "after a vigorous effort has been made to obtain the solution without the book."

Lectures on Bacteria. By A. De Bary. Second Improved Edition. Authorized Translation by Henry E. F. Garnsey. Revised by I. B. Balfour, F.R.S. (Oxford: Clarendon Press, 1887.)

THIS work is in the main an abridgment of a number of lectures, some of which were delivered in a connected series as a University course, others as occasional and separate addresses. The author's aim is to set forth the present state of our knowledge respecting the objects included under the name of Bacteria. Having dealt with cell-forms, cell-unions, and cell-groupings, he describes the course of development of Bacteria, and then proceeds to discuss questions as to the position of Bacteria in the organic world, and as to their origin and distribution. A chapter on vegetative processes is followed by one on the relation of Bacteria to, and their effect upon, their substratum; and this leads to an account of the forms which excite fermentation, and of parasitic Bacteria. The remaining chapters are on the harmless parasites of warm-blooded animals, on anthrax and fowl-cholera, on the

causal connection between parasitic Bacteria and infectious diseases, especially in warm-blooded animals, and on diseases caused by Bacteria in the lower animals and in plants. The work will be very useful to all who may wish to obtain "a general view" of this important subject. It has been well translated, and we may note that a valuable list of publications relating to Bacteria is given at the end of the volume.

Mattie's Secret. By Émile Desmaux. (London: George Routledge and Sons, 1887.)

THIS book is evidently a French work very well translated into English. It is practically a book of delightful gossip, touching on many important points of science; while theoretically it is a pleasing story of a sister who devotes her time to her little brother driven from school and books by approaching blindness. The scientific part opens with the explosion of fire-damp, and goes on to the history of coal, how it is found, in what shapes; and then to the coal-mine itself, how the work is done, and the precautions which have to be taken. Next follows the history of diamonds, what they are, how they are shaped into different forms; and then comes graphite manufactured into pencils. The history of beer here follows, how it is prepared, and its use. Then the author explains torpedoes and torpedo-boats, how they are worked, and the method of launching the torpedo. Glycerine, dynamite, and gunpowder, their dangerous properties, and how they are prepared, are next referred to, and this is followed by an introduction to the phenomena of sound.

The book contains a hundred good illustrations showing the different scientific processes, and it is thoroughly interesting throughout.

The question arises whether fairy tales of science are not as interesting to children as fairy tales of the ordinary description. The author is evidently of this opinion, and we are inclined to agree with him. A. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Politics and the Presidency of the Royal Society.

YOUR leader of last week reminds me not a little of one of those days that begin somewhat brightly but end with a thunderstorm. As a Fellow of the Royal Society, I fail to see what our President has done to incur the reprobation of the writer of this article. I will take in order the two charges brought against him. Of these, the first is that he became President of the Victoria Institute, the second being that he has allowed himself to be returned as member of Parliament for his own University.

I do not fancy the writer means to assert that the predecessors of Prof. Stokes, more than one of whom held strong views connected with theology, virtually laid these aside during their tenure of office. At any rate, they gave ample expression to them both before and after this tenure. I gather that the objection rather is that Prof. Stokes, during his tenure of office, became President of another Society—the Victoria Institute. Now, Sir, I can see at once an objection to the President of the Royal Society being at the same time President of any of the other scientific Societies, such as the Astronomical, the Physical, the Chemical, or the Zoological. But I confess I fail to see any objection to his taking office in a Philosophical Society, which treats of subjects not really connected with science.

It may perhaps be thought that the Victoria Institute was deficient in breadth of view, and I think that until lately it was open to this objection. But I have reason to think that Prof. Stokes has infused into it a better spirit, and his admirable opening address to this Society has, if I mistake not, appeared in your columns.

In this address he acts entirely the part of a peacemaker, endeavouring to show that the conclusions of science cannot be held to come into collision with what may be regarded as the essential truths of the Christian religion. It is probable that a minority of Fellows of the Royal Society may believe that certain scientific doctrines have disposed of the claims of Christianity. Must, therefore, the President be precluded from going to church during his tenure of office? Unquestionably the going to church implies taking part in a public action about which the opinions of the Fellows could be divided.

It is in truth exceedingly difficult, if not impossible, to formulate a principle which shall extinguish the peculiarities of one individual while it leaves untouched the field around him representing the rights and privileges of others. The thing was tried once before in the time of Darius the Mede, but the results of the experiment were not of an encouraging nature.

I come now to the second and most important charge against our President. And here I confess I cannot help being a little amused at the writer's dread that the President will be hunted out of his scientific chair at all inconvenient hours, and driven to his seat at St. Stephen's by one of the Whips of the House. And I confess that I am equally amused at the thought of the Royal Society suffering the fearful political degradation depicted by the writer, entertaining as I do the most complete confidence in the integrity of this Society. I grant freely that under ordinary circumstances it is undesirable that the President of the Royal Society should enter the House of Commons. But these are no ordinary times, and we are now engaged in a struggle that means more than mere party warfare.

I do not wish to introduce politics into these pages, but I may state that in my opinion, and I think I may say in that of many Fellows of the Royal Society, the question just now is one between law and anarchy. But in a state of anarchy, what will suffer more than knowledge? In such a state will there be leisure to investigate—leisure even to dispute? And if this be so, should not Culture, which is more threatened than anything else, raise her voice in the Legislature and do what in her lies to prevent this deplorable consummation?

Surely it is this grave question, rather than any wish to represent the every-day interests of science, that has induced our President to enter the House. He has chosen to be an Englishman first, and a man of science afterwards. Who will blame him for this? BALFOUR STEWART.

THE able article which appeared in your last number (p. 49) under the title of "Politics and the Presidency of the Royal Society," raises a question of such magnitude, not only in its relation to science, but also to many other branches of human activity, that I trust to your courtesy and impartiality to give me an opportunity of briefly indicating some considerations calculated to lead to a conclusion different from that at which the writer of the article in question has arrived.

The Royal Society is composed of members who differ from one another in their views on political and many other subjects; nay, more, of men who differ from one another in their views on many scientific subjects. Their devotion to the advancement of natural knowledge is the common ground on which they meet.

The political opinions of our President are entirely unknown to us officially, and it may confidently be asserted that he is as highly esteemed and valued as President by those among us who may happen privately to differ from him widely in politics as by those who entertain similar political opinions to his own. His action in political matters concerns us as little as his opinions. No doubt we should be concerned if he were to undertake any duties of so engrossing a kind as to prevent him from fully discharging the duties of President, but we should be so equally if the additional work were not political.

It is conceivable, though we will hope not very likely, that at some future time the Society might have to return a member to the House of Commons; the Society would then be in a similar position to that in which several of our Universities are placed; the arguments used by the writer of the article might then be applied.

Our President cannot, however, be supposed to have entered

the House as the political representative of the Royal Society, for two reasons: first, because the Society has, in its corporate capacity, notoriously no political opinions to be represented; and, secondly, because we have not sent him to the House.

ALEX. W. WILLIAMSON.

High Pitfold, Haslemere, November 19.

"The Conspiracy of Silence."

THOUGH I am sorry to have misunderstood the meaning of the Duke of Argyll in his "Great Lesson," when I supposed him to accuse scientific men of virtually conspiring to suppress any unwelcome truth, I think I am not without excuse. Certainly I was not alone in the illusion, and I believe that many would even now say that the Duke of Argyll—in writing some of the passages which I quoted, and in using such phrases as "reluctant to admit such an error in the great idol," "slow and sulky acquiescence," "reluctantly, almost sulkily," "a grudging silence," not to quote any others—has certainly not expressed with felicity the lesson which he intended to inculcate. Further, in regard to the special instance brought forward by the Duke (that of Mr. Murray's paper) it does not appear to me that he has even now established his charge. The Duke states that he has seen a letter, written by the late Sir Wyville Thomson, most strongly urging Mr. Murray to withdraw the paper which he had sent to the Royal Society of Edinburgh. The Duke further tells us candidly that no reason is alleged in the letter. Hence, Sir Wyville Thomson's motive is a matter of inference only. I hope I shall not give offence to my friend Mr. Murray if I suggest that it may have been different from that which the Duke supposes. In 1877, so far as I can ascertain, Mr. Murray had not had much practice in writing papers. There is an art in this, which we have to learn by practice and the kindly criticism of our manuscripts by friends. As the best meat may be spoiled by an inexperienced cook, so the best material may be damaged by an inexperienced author. Sir Wyville Thomson would naturally feel very sensitive about any communications bearing the names of members of the *Challenger* Expedition, for if among its first-fruits had been a paper unsatisfactory either as to style or arrangement, yet controverting the deliberate conclusions of those hardly less well qualified to judge, a spirit of criticism and of distrust as to the thoroughness of the work of the Expedition would have been aroused. Of course this is an hypothesis only, which I trust Mr. Murray will forgive me for making, but I can assure him that I am conscious of my own youthful imperfections (not to mention the mistakes of maturer years), and I submit that it is at least as good as the Duke's, and more charitable to the memory of Sir Wyville Thomson.

In regard to the new case which the Duke of Argyll brings forward, and with which he connects my name, he is not quite accurate in his facts and is wrong in his inference. Mr. Guppy's paper was not "refused" by the Geological Society of London. The President has the power in certain cases, and under certain conditions, to refuse to put down for reading a paper written by a Fellow. I did not exercise that power. The Council, after a paper has been read, can refuse to print it. As Mr. Guppy's paper was never read, obviously this did not happen. Probably the circumstances were as follows,—I say probably, for I have no distinct recollection of them. Mr. Guppy's paper may have been sent, as is often done, for an informal expression of opinion as to whether the paper seemed suitable for the Society's consideration. In such case it would be shown either to one of the secretaries or to the President, and the opinion, favourable or otherwise, communicated to the author, who would then be free to act as he thought best. Now, if Mr. Guppy's paper was identical with that printed in the Proceedings of the Royal Society of Edinburgh (vol. xiii. p. 857) I have no doubt that my answer was to this effect: that it contained so much matter which belonged rather to natural history than to geology that I thought it was likely to suffer much excision before it was printed in our Journal, especially at that time, and was more suited for a Society of a wider scope than our own. I have again referred to the paper, and, without entering upon its merits, of which I am fully sensible, am still of opinion that, while it is in its place in the Proceedings of a Royal Society which includes all branches of science, it would have to be considerably abridged to fit it for those of a Geological Society. Of course that is only my opinion, but after full ten years' experience, eight of them as an officer, on the Council of the Geological Society of London, I may claim some knowledge of the principles on which that body acts. Moreover, at that time the Society was suffering from a falling off in revenue, with no corresponding decline in the number of papers which it was invited to publish. This I knew had compelled the Council to exceptional strictness. The difficulties of the Society were indeed so considerable that I commented on them in my address on quitting office in 1886, expressing at the same time my own view as to how they should be met. But though, as I have said, I have no clear recollection of the circumstances, I can speak positively of one thing, that if in any way I discouraged Mr. Guppy from communicating his paper it was not because I "smelt a heresy." It is something quite new for me to stand accused of being a prompt suppresser of heresies. My orthodoxy has not always been considered unimpeachable among the clergy, and surely my scientific papers are not generally on the side of "established views."

To conclude, the Duke still—and this is our special complaint—treats the matter rather according to ecclesiastical than to scientific methods. He is fully persuaded of the excellence of Mr. Murray's hypothesis, and considers it to be "one of those discoveries in science which are self-luminous," and "must carry conviction to all." Very well, but there are some people, not very few in number, who do not share his opinion. He cannot understand that our doubts can be due to anything else but "prepossession," which has prevented our minds from being "alive to the breadth and sweep of the questions at issue." I humbly reply that this is not the case; that we claim to exercise the right of private judgment, and decline to submit to any pope, from whatever part of the United Kingdom he may issue his Bull.

T. G. BONNEY.

Instability of Freshly-Magnetized Needles.

YOUR reviewer objects to a statement in my "Theory of Magnetic Measurements," to the effect that freshly-magnetized needles give untrustworthy readings for several minutes after magnetization (see NATURE, vol. xxxvi. p. 316). In reply to his statement that this is contrary to experience, I wish to say that it is not contrary to my experience. In working with two 8-inch needles I continually observed this phenomenon for years, and it was so marked that I could not feel satisfied to omit the precaution which the critic condemns. I know of one other observer who has had a similar experience with another needle. My needles were not very hard, and perhaps this may have had to do with the phenomenon.

It is not desirable to make any reply to criticisms, even though they seem not quite fairly taken, but it ought to be suggested that those who are unable to apply general formulæ to a special form of instrument after they have been shown how to apply them to a similar instrument might perhaps meet with more success in some other line of business.

FRANCIS E. NIPHER.

IN the passage to which Prof. Nipher refers I contrasted what seemed to me the excessive precautions prescribed in the directions for obtaining the dip with a rather rough-and-ready method of manipulation elsewhere suggested by him. That the magnetic axis of a piece of steel may shift is possible. My criticism was directed to the question as to whether, as a matter of experience, such a shift is a cause of error of practical importance in the determination of the dip. It would, therefore, be interesting if Prof. Nipher would publish the details of the observations on which his conclusion is based, so that the extent to which a measurement of the inclination may be rendered untrustworthy by not waiting for some minutes after magnetizing the needle may be in evidence. Meanwhile it may be well that I should define my own views on the matter.

On looking through the observations made in the magnetic survey of Missouri, which Prof. Nipher is conducting, I find that the dips obtained with different needles vary widely. Thus, taking the last Report to which I have access, in which the work of the year 1881 is described (Trans. Acad. Sci. St. Louis, vol. iv. No. 3, p. 480), the dip was determined with two needles at fifteen stations. At seven of these the difference between the results obtained by the two needles was equal to, or greater than, 4'. At one station it was 24'·8, and at others 17'·2, 11'·7, 9'·4, and 8'·9 respectively. If these are examples of trustworthy readings (and from their publication we must suppose that they are so), and if the differences obtained when the observations are untrustworthy on account of the shift of the magnetic axis are greater

than these, Prof. Nipher's experience is totally at variance with my own.

During the last four years, Dr. Thorpe and I, assisted at some Scotch stations by Mr. A. P. Laurie, have made about three hundred independent determinations of the dip. The observations have been made in the course of a magnetic survey of the United Kingdom at various stations, in all weathers, and without any delay after magnetization. We have used two sets of $3\frac{1}{2}$-inch needles, and have made determinations with two needles at nearly all the stations. In no single case does the difference between the results obtained with two needles amount to 4′. In three or four cases only does it exceed 3′, while differences of 2′ are relatively rare. Thus in forty-six Scotch stations (for which alone the results are fully tabulated) the difference exceeded 2′ in nine cases only. Mr. Welsh, in the survey of Scotland, recorded in the Report of the British Association for 1859, and the Rev. S. Perry obtained results in which the discordance between the two needles was of the same order of magnitude as in our own work.

If, therefore, Prof. Nipher refers to differences comparable with those exhibited by his published observations, they are contrary to the experience of observers working with better constructed instruments. If he refers to errors smaller but observed with an instrument with which a discordance between the two needles of from 10′ to 24′ can be tolerated, I should doubt if his apparatus is suitable for the elucidation of the point. If he is in possession of good evidence that, in the case of needles for which the maximum difference between observations made without delay after magnetization is not greater than 4′, the accord between them is improved by delay, the matter is no doubt of interest for observatory work. My own experience has been chiefly gained in the field, and I can only say that I have never noticed anything which led me to suspect such a cause of error.

It is, however, capable of proof that the improvement can be but small, as results obtained in a laboratory and without the precaution Prof. Nipher insists on agree nearly to the limit to which the instrument can be read.

This can be illustrated from the observations made by Dr. Thorpe and myself at Kew for the purpose of testing our survey instruments. At first we employed only a circle by Dover, No. 74. The following observations were made with it in the magnetic house by Mr. Baker, the Chief Assistant, and ourselves :—

Date, 1884.	Observer.	Needle.	Dip.	Mean.
June 24	Baker	1	67° 36′·8	67° 36′·6
		2	36·5	
July 18	Thorpe	1	67 36·1	67 36·0
		2	36 0	
,, 19	Rücker	1	67 36·5	67 36·3
		2	36·1	

These results were about 2′ lower than those obtained by Mr. Baker with the Kew instrument about the same time, but whatever the cause of this may have been they certainly do not convey the idea of instability.

Lately we have again compared No. 74 with the Kew instrument and with Dover No. 83, which belongs to the Science and Art Department. Thus six needles (two belonging to each instrument) were used. I quote the results, not as in any way extraordinary, but as types of the accuracy usually obtained by competent observers with good instruments :—

Date, 1887	Observer.	Instrument.	Needle.	Dip.	Mean.
Sept. 30	Rücker	Dover 74	1	67° 35′·4	67° 35′·1
			2	34·8	
Oct. 11	Thorpe	Dover 83	1	67 33·9	67 34·4
			2	34·9	
,, 13	,,	,,	1	67 36·0	67 36·0
			2	36·1	
,, 18	,,	,,	1	67 34·2	67 34·2
			2	34·2	
,, 19	Rücker	Dover 74	1	67 35·0	67 34·2
			2	33·4	

Mr. Baker's observations with the Kew instrument are again (as is shown below) a little higher than those obtained with Dover's circles.

Date, 1887.	Needle.	Dip.	Mean.
Sept. 22	1	67° 35′·3	67° 35′·6
	2	36·0	
Sept. 24	1	67 37·6	67 37·5
	2	37·4	
Oct. 25	1	67 38·8	67 37·9
	2	37·0	

Judging then from these results and from our own field observations, I do not believe that, apart from small instrumental errors, the error of the determination of the dip with a single needle, and without any delay after magnetization, will in general exceed ± 1′. Under unfavourable circumstances it may reach ± 1′·5. These estimates embrace not only the assumed instability of the magnetic axis, but that and all other causes of error combined. That some effect of the kind referred to by Prof. Nipher, which only affects the result below these limits, may exist even in good needles is perhaps possible. As the verniers of the circles only read to minutes it could not be detected except by making a number of observations for the purpose.

In conclusion I may add that for good dip observations good instruments are essential. In a preliminary survey in the neighbourhood of Mull, made in 1883, we employed an older instrument which had been a good deal used in a laboratory. The measurements made with it were less satisfactory than those above described, but the largest difference between the two needles did not exceed 6′. For survey purposes small needles and circles seem on all accounts better than the large ones used by Prof. Nipher. ARTHUR W. RÜCKER.

South Kensington, November 2.

Greek Geometry.

IN the notice of the last part of "Greek Geometry from Thales to Euclid" (NATURE, vol. xxxiv. p. 548) I was uncertain whether Dr. Allman intended it to be Part vii. or not; I observe from the extract before me (*Hermathena*, No. xiii., 1887, vol. vi. pp. 269–78) that the present part is so entitled. The author's plan led him to the temporary omission of Theætetus of Athens, a pupil of Theodorus of Cyrene, and also a disciple of Socrates, who greatly advanced the science of geometry. How his gifts and genius impressed both Socrates and Plato is well known from the dialogue which bears his name. From an analysis which our author makes of part of this dialogue it appears that Theætetus, in addition to Eudoxus and the Pythagoreans, was one of the original thinkers to whom Euclid was most indebted in the composition of the "Elements." Dr. Allman thus recapitulates :—"In the former parts of this paper we have seen that we owe to the Pythagoreans the substance of the first, second, and fourth books, also the doctrine of proportion and of the similarity of figures, together with the discoveries respecting the *application*, *excess*, and *defect* of areas, the subject-matter of the sixth book. The theorems arrived at, however, were proved for commensurable magnitudes only, and assumed to hold good for all. We have seen, further, that the doctrine of proportion, treated in a general manner, so as to include incommensurables (Book v.), and consequently the recasting of Book vi. and also the method of exhaustions (Book xii.) were the work of Eudoxus. If we are asked now: In what portion of the 'Elements' does the work of Theætetus survive? we answer: Since Books vii., viii., and ix. treat of numbers, and our question concerns geometry; and since the substance of Book xi., containing, as it does, the basis of the geometry of volumes, is probably of ancient date, we are led to seek for the work of Theætetus in Books x. and xii.; and it is precisely with the subjects of these books that the extracts (*d*), (*e*), and (*f*) are concerned."

The extract (*d*) states that Euclid, x. 9, is attributed to Theætetus by an anonymous scholiast, probably Proclus; extract (*e*) translates, discusses, and illustrates fully the passage (147 D–148 B) of the Dialogue; and extract (*f*) mentions the statement by Suidas, that our geometer taught at Heraclea, and that he first wrote on "the five solids," as they are called. Attention is

drawn to the difference in expression employed by Proclus, viz. that Euclid *arranged* many works of Eudoxus, and *completed* many of those of Theætetus, from which Dr. Allman infers that, "whereas the bulk of the fifth and twelfth books is due to Eudoxus; on the other hand, Theætetus laid the foundation only of the doctrine of incommensurables as treated in the tenth book. In like manner from (*f*) we infer that the thirteenth book, treating of the regular solids, is based on the theorems discovered by Theætetus; but it contains, probably, a recapitulation, at least partial, of the work of Aristæus" [cf. NATURE, *ubi supra*].

The author, in conclusion, draws the inference that the principal part of the original work of Euclid himself is to be found in the tenth book. "De Morgan suspected that in this book some definite object was sought, and suggested that the classification of incommensurable quantities contained in it was undertaken in the hope of determining thereby the ratio of the circumference of the circle to its diameter, and thus solving the vexed question of its quadrature. It is more probable, however, that the object proposed concerned rather the subject of Book xiii., and had reference to the determination of the ratios between the edges of the regular solids and the radius of the circumscribed sphere, ratios which in all cases are irrational. In this way is seen, on the one hand, the connection which exists between the two parts of the work of Theætetus, and, on the other, light is thrown on the tradition handed down by Proclus, that Euclid proposed to himself the construction of the so-called Platonic bodies as the final axiom of his systematization of the 'Elements.'" Here for the present I take leave of the author. I have read his several parts as they have appeared with very great interest, and have endeavoured, without going far into technical details, to indicate the results arrived at, and I hope that some will have been induced to go to the fountain-head for undiluted draughts from this refreshing stream. I need only repeat the expression of the wish, more than once previously uttered, that the several papers may be collected into a handy volume, in which case they will fitly go side by side with the works of Bretschneider, Cantor, Tannery, and other distinguished labourers in the same field. R. T.

The Chromosphere.

HAVING lately devised a spectroscope with two small sextant telescopes and two small prisms, one of "extra dense" glass by Hilger, I attached it to a 2½-inch telescope, and tried its powers on the sun on the 6th inst., with the result that not only were the rays C and D^3 easily visible as bright lines, but I also found that by opening the slit and keeping the brighter part of the spectrum out of view I could see the actual ragged surface of the "storm-tossed sea of hydrogen."

I found the depth of the chromosphere to be about 10″, by estimating the length of the bright line when exactly tangential to the limb.

This result shows what is possible with small instrumental means, though probably much was due to an exceptionally clear sky. JOHN EVERSHED, JUN.

Perception of Colour.

IN answer to Mr. T. W. Backhouse, I would suggest that he should use the spectroscope in the following manner. Hold it between the luminous object (moon or street lamp) and the eye at a distance of about 12 or 15 inches from the latter, so that only part of the spectrum is seen. Then remove the spectroscope sideways, and pass it quickly through its old position. A flash of coloured light will be seen, and no matter what may be the direction of the spectrum with reference to the line of motion the flash will always be seen to travel from the red end towards the blue end. Each part of the spectrum can be examined separately.

Whether this phenomenon is due to a later perception or longer retention of the blue light as compared with the red I cannot at present say, but I think it is independent of the intensities. C. E. STROMEYER.

Swifts.

ON June 19, and again on June 21 last, in the evening, I watched a vast concourse of swifts flying over this town. They slowly soared upwards, shrieking and striking at each other, and at last went so far up in the sky as to look like a cloud of black gnats. I watched them till dusk, when their faint cries were still audible, and when these had died away in the distance I waited long for the birds to descend, but they did not, probably because they were old birds which had been sitting all day, and were glad of an opportunity to stretch their long wings in a few hours' flight. No great height would necessarily be attained by the birds during the short midsummer nights. I noticed on several subsequent evenings that at least some of the swifts of the town did not stay up till dusk; but I am not the less positive that on June 19 and 21 they spent the night in the sky.

Note on a Madras Micrococcus.

THE sole charge of a Presidential Museum and the study of that high-road to pathological eminence, bacteriology, are unfortunately not compatible, but I have not been able to resist the rough investigation of a phenomenon which stands prominently out before my eyes as I write. It consists of a thin, homogeneous, pale pink pellicle, covering the *chunam* (shell-lime) walls of my house on the side exposed to the heavy monsoon rain, which is at present varying the monotony of our "fine sunny days," which so impress our energetic cold-weather visitors, who learn all about India from Calcutta to Cape Comorin in a three weeks' tour. So evenly is the pink-coloured material distributed in my library, that its walls look as if they had been painted on one side, and whitewashed on the other three sides. This coloration, which is well known in Madras, is, I believe, commonly attributed to some occult chemical action on the lime, but a cover-glass specimen stained with methylene blue, and examined with a ⅛-inch objective, decides at a glance that it is caused by a Micrococcus, which, in its microscopical appearance, presents nothing remarkable.

The mode of growth of this organism on or in artificial nutrient media I have not attempted to investigate, but I notice that white lead does not agree with it, as its growth ceases abruptly at the painted framework of the doors and windows.

As I cannot find any description, in the reference-books at my disposal, of a Micrococcus which corresponds to the one here described, I christen it provisionally *Micrococcus madraspatanus*, Madraspatan being the old name of Madras, which is, according to Lassen, a corruption of Manda-rājya, meaning "realm of the stupid." EDGAR THURSTON.

Government Central Museum, Madras, October 26.

Catharinea undulata.

IN October 1886 I found, in Hertfordshire, two specimens of *Catharinea undulata*, Web. et Mohr., bearing fruit in the axils of the leaves; those specimens I unfortunately lost.

When this summer in Norway, I had the good fortune and pleasure of meeting Prof. S. O. Lindberg, of Helsingfors, and I mentioned the fact of the discovery to him. He then told me that similar specimens had been found in Norway some little time before, and described under the name of *C. anomola*, Lindberg and Bryhn. In consequence of my conversation with Prof. Lindberg I looked again this autumn for specimens similar to those I had found last year, and after some little search I found some half-dozen or so near the same spot where I had found them last year.

The specimens I now have in my possession bear fruit at the apex of the stem, and also one, or sometimes two, setæ in axils of leaves below the apex. These pleurocarpous setæ differ from the acrocarpous by being twisted in a spiral manner, not being straight as the acrocarpous fruits are; they are inserted in a vaginula in the axil of the leaf, without any perichætial leaves.

I should be glad if bryologists generally would look out for specimens of this form. I should also consider it a great favour if any collectors who may find specimens would let me know, and provide me with an accurate description, or send me the specimens for inspection. Specimens should be preserved in strong methylated spirit, otherwise it may be difficult to verify some important details.

There is a brief reference to the Norwegian specimens in the *Botanische Centralblatt*, Band xxix. p. 2, 1887; the full description is, I believe, to be found in the *Botaniska Notiser*, 1886, p. 157; the latter I have not yet been able to obtain access to, though I hope to do so soon. J. REYNOLDS VAIZEY.

Botanical Laboratory, Cambridge, November 18.

RESEARCHES ON METEORITES.[1]

II.

The Cases of Nova Orionis and R Geminorum.

THE stars with bright carbon flutings, the same as those seen in comets, are not limited to first-magnitude stars, such as α Orionis, but include at least one new star, Nova Orionis. Because the latter star lasted but a short time we might expect the phenomena presented to be different from those found in the first-magnitude star, which is a variable, like others with similar composite spectra. Practically there is little difference, for in α Orionis, α Herculis, and others of that type, we find well-marked dark absorption flutings of manganese, as well as line-absorption of sodium and magnesium.[2] The absorptions are not so well developed in the Nova, for the reason, perhaps, that condensation due to gravity had not taken place to such a great extent, so that the heat of the stones themselves was not so great, and further because the local absorption around each meteorite would be cloaked by the bright radiation of the interspaces, which gives, as in comets, the maximum intensity to the bright fluting, wave-length 517. In R Geminorum the demonstration of the same meteoric constitution, but without the strong absorption, is given by the fact that in that star so much of the light proceeds from the vapour produced by the meteorites, and from the carbon in the interspaces, that the carbon flutings and the bright lines of barium and strontium, and other substances present in meteorites, are visible at the same time, exactly as they are seen in the glow over a meteorite in an experimental tube, in which, as the pressure is reduced, the edges alone of the carbon flutings are visible, and put on the appearance of bright lines, almost exactly resembling the bright lines of the heated meteorites.

I give on a map the spectra of these two stars side by side with the bright flutings of carbon and the dark flutings of manganese with a view of showing that, both in the Nova and the fi st magnitude one in the same constellation, many of the phenomena are the same and are therefore probably produced by the same cause. Some time after Dr. Copeland's original observations of this star were published, it was pointed out, by

MAP 4.—Spectra of nebulæ compared with the spectra of hydrogen, cool magnesium, and meteorite glow.

Dunér, Vogel, and others, that some of the bright parts of the spectrum observed by him were really coincident with the bright parts of the spectrum of α Orionis; this, of course, is beyond question. But in addition to these bright spaces Dr. Copeland gives some bright regions which, I think, have not been touched by the arguments of Vogel and Dunér above referred to. It will be observed that in the case of R Geminorum, given on the same map as Nova and α Orionis, the bright lines correspond almost exactly with the bright spaces shown in the above-named stars and certain lines seen in meteorites—that is to say, a meteorite glow, when the carbon spectrum is bright, gives us all the lines recorded in the spectrum of the star, showing that some of the lines correspond with the brightest flûtings of carbon.

There can be no question, I think, that in R Geminorum we have another stage, doubtless a prior stage, of the life-history not only of the Nova, but of α Orionis itself.

[1] Continued from p. 61.
[2] The manganese absorptions agree with some of the manganese flutings seen in the Bessemer flame by Marshall Watts (*Phil. Mag.* February 1873).

III. The spectra of meteorites glowing in tubes with the bright lines observed in celestial bodies—

(α) Comparison with the lines seen in nebulæ when C and F (bright) are either present or absent.

(β) Comparison with bright lines (not associated with flutings) seen in stars.

α. "Nebulæ."

Only seven lines in all have been recorded up to the present in the spectra of nebulæ, three of which coincide with lines in the spectrum of hydrogen and three correspond to lines in magnesium. The magnesium lines represented are the ultra-violet low-temperature line at 373, the line at 470, and the remnant of the magnesium fluting at 500, the brightest part of the spectrum at the temperature of the bunsen burner. The hydrogen lines are *h*, F, and Hγ (434). Sometimes the 500 line is seen alone, but it is generally associated with F and a

line at 495. The remaining lines do not all appear in one nebula, but are associated one by one with the other three lines. The lines at 500 and 495 and F have been seen in the glow of the Dhurmsala meteorite when heated, but the origin of 495 has not yet been determined.

The result of this comparison then is that the nebula spectrum is as closely associated with a meteorite glowing very gently in a very tenuous atmosphere given off by itself as is the spectrum of a comet near the sun by a meteorite glowing in a denser one also given off by itself when more highly heated.

Further, it has been seen that the nebula spectrum was exactly reproduced in the comets of 1866 and 1867, when away from the sun. As the collision of meteorites is accepted for the explanation of the phenomena in one case, it must, *faute de mieux*, be accepted for the other. The well-known constituents of meteorites, especially olivine, fully explain all the spectroscopic phenomena presented by luminous meteors, comets, and nebulæ.

I published many years ago an experiment in which I had found that the gases evolved from meteorites under some conditions gave us the spectrum of hydrogen and under others the spectrum of carbon; but in the globes I then used I was not enabled to study the spectrum of the glow itself.

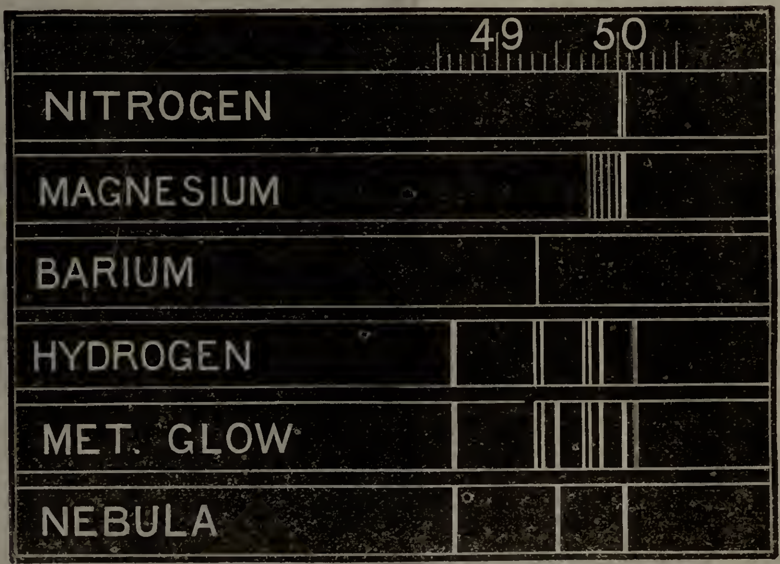
I should add that the line at 495 makes its appearance much more rarely than the one at 500, in meteorite glows.

β. "Stars" with bright lines.

On reference to the maps which I exhibit to the Society, though they and the discussion of them are yet incomplete, it will be seen that the principal lines which are seen bright in star spectra are, if we make due allowance for the discrepancies likely to occur in observations attended with great difficulties, lines which either have been observed in the vapours and gases given off by meteorites in vacuum-tubes or which we might expect to see in a combined series of observations on meteorites having different chemical constituents. Among these lines are H_α, H_β, H_γ, H_δ, 464, 540, 570, 580, 587; in one case (1st Cygnus) there are lines at 5065 and 5268, the latter due to iron. The difficulties attending this part of the inquiry are referred to subsequently, and it must be understood that in the absence of a detailed discussion especially of the spectra of the "Novas," which I have not yet completed, the opinion I express in the next part of this preliminary notice with regard to bright-line stars must be regarded rather as suggestions than as final conclusions.

Discussion of the Maps showing the Bright Lines visible in Stars and Nebulæ.

It results from the discussion of the bright lines seen, whether associated with the bright lines C and F of hydrogen or not,



MAP 5.—Shows the positions of three of the nebula lines as compared with well-known lines.

that, while on the one hand we have a class of bodies—the nebulæ—which give us the lines visible at the lowest temperature of chemical elements known to exist in meteorites, we have in the other class—the "stars" with bright lines—those lines visible at somewhat higher temperatures in meteorites. In the stars with bright lines the two most important lines, which have been separately mapped by Vogel,[1] occur at 540 and 582. The mean readings of all the observations gives the positions of these lines as 540 and 580. In an experiment on the glow of a meteorite rich in manganese, the line of Mn at 5395, easily seen at the temperature of the bunsen, is distinctly seen in addition to the structure-spectrum of hydrogen. There is reasonable ground therefore for supposing that this line, the only one of the iron group of metals visible at the temperature of the bunsen, may be the origin of one of the two lines seen alone in the spectrum of these "stars." It will be seen that in the map it has been easy to arrange all the bright lines hitherto seen in stars into one order, in which we begin with this line of manganese, and a line of iron seen at the temperature of the oxy-coal-gas flame, the wave-length of which is 579. As other lines indicating other substances are added to these fundamental ones, we pass from those stars in which C and F are not visible to those in which they make their appearance. Here, however, it is necessary to move with caution, because it may be that we are in presence of some of the lines visible in the structure-spectrum of hydrogen. The chief lines of hydrogen, as seen in the end-on tube when the conditions are such that C and F are not visible, have been already stated. Some of the lines observed in these stars, even the one at 540, have been found to be very nearly coincident with bright lines seen in the structure-spectrum, as well as with lines seen in the spectra of meteorites.

The suggestion, therefore, that some of the lines seen in bright-line stars are lines of cool hydrogen must be noted, although there are strong grounds for rejecting it, as will shortly appear. One objection is that strong lines of the H structure at 607–610 and 574 have not been recorded in star spectra with those at 540 and 580.

In the nebulæ (see Map 5) we deal chiefly with lines seen in the spectrum of magnesium at the lowest temperature; and these, as far as observations go, have not yet been associated with the lines at 540 and 580 to which reference has just been made, although they may or may not be associated with the bright lines C and F of hydrogen. In the nebulæ, however, no lines coincident with the lines of cool hydrogen have been observed. It will be seen, there-

[1] *Potsdam Observations*, vol. iv. No. 14.

fore, that we have here again strong ground for rejecting the view that the lines seen in "stars" at 540 and 580 are due to cool H, for since hydrogen is common to both nebulæ and stars, there is no reason why structure lines should occur in "stars" any more than in nebulæ.

Another ground for rejecting cool hydrogen as the origin of any of the lines in "stars" is that the structure-spectrum of hydrogen is only seen in confined glows, which is just the condition which cannot occur in space.

At the same time, the apparent coincidences of many meteorite lines with structure lines of hydrogen greatly increases the difficulties of laboratory work; in fact, the structure-spectrum of hydrogen is to observations of meteorite glows in the laboratory what continuous spectrum is to observations of bright lines in stars.

If it be agreed that we are not dealing with cool hydrogen, then it will follow that the only difference between celestial bodies with bright lines in their spectra comes from no difference of origin or chemical constitution, but from a difference of temperature.

At one point in these researches I was under the impression that the differences in the systems of bright lines seen in the nebulæ and the bright-line stars might arise from a preponderance of irons or stones in the swarms. But I was led to abandon this idea, not only by the observation of the meteoritic glows, but by the consideration that even telescopically the "stars" in question are more condensed than the nebulæ.

The spectrum of the nebulæ, except in some cases, is associated with a certain amount of continuous spectrum, and meteorites glowing at a low temperature would be competent to give the continuous spectrum with its highest intensity in the yellow part of the spectrum; so that in this way we should understand that lines due to any gas or vapour in that part would be very much more likely to escape record than those in the part of the spectrum which the continuous spectrum hardly reaches. The general absence, however, of bright lines of metallic vapours, except 495 and 500, and of the bright lines of hydrogen, evidently justifies the conclusion that we are here in presence of those bodies in celestial space, connected with which the temperature and the electrical excitation are at the minimum, and it is very remarkable how the lines seen in a Geissler tube under the conditions stated, when either magnesium, or olivine, or other meteoric constituents are made to glow, should appear, one may almost say, indiscriminately among the orders of bodies in the heavens which up to the present time have been regarded as so utterly different in plan and structure as stars and nebulæ.

The records of purely continuous spectra in the case of many nebulæ, as, for example, the Great Nebula in Andromeda, is in all probability an indication of our inability to observe them properly. For a nebula to give a perfectly continuous spectrum, it is evident that the component meteorites must be incandescent, but still at a lower temperature than that required to give bright lines. Now, the Mg line 500 is seen in some of the faintest nebulæ, where there is little or no continuous spectrum, and it therefore seems likely that these are at a lower temperature than the nebulæ said to give perfectly continuous spectra. This being so, it is difficult to believe that other lines, which require a somewhat higher temperature for their existence than the line at 500, do not become visible at this increased temperature.

There can be little doubt that when our instrumental appliances and observing conditions become more perfect it will be found that the so-called continuous spectra are really discontinuous. There is, indeed, an element of doubt as regards some of the existing observations; thus, the spectrum of the companion to the Great Nebula in Andromeda appears to end abruptly in the orange, and throughout its length is not uniform, but is evidently crossed by lines of absorption or by bright lines (Huggins, Phil. Trans. vol. cliv. p. 441).

Again, the Great Nebula in Andromeda is generally regarded as having a continuous spectrum pure and simple, but an observer at Yale College (name not stated) has observed three bright lines in its spectrum (*Observatory*, vol. viii. p. 385). The lines are—the F line of hydrogen, and two other lines at wave-lengths 5312·5 and 5594·0. The latter two lines are mentioned by the same observer as bright lines in γ Cassiopeiæ and β Lyræ, and are recorded by Sherman (*Astr. Nach.*, No. 2591) as bright lines in these stars and in Nova Andromedæ. No other observations with which I am acquainted give these two lines in γ Cassiopeiæ or β Lyræ, but Maunder (*Monthly Notices*, vol. xlvi. p. 20) gives them as two of the lines seen in Nova Andromedæ. It is possible, therefore, that the two lines in question, in the Yale College observation, had their origin in Nova Andromedæ; at all events there is no evidence to show that they are visible in the Great Nebula of Andromeda under normal conditions.

It is not impossible that the lines at 540 and 580 may be eventually traced in some of the brightest nebulæ, since these are apparently the lines next in order, as regards temperature, to the Mg line 500.

It is right that I should here point out that some observers of bright lines in these so-called stars have recorded a line in the yellow which they affirm to be in the position of D_3; while on the other hand, in my experiments on meteorites, whether in the glow or in the air, I have seen no line occupying this position.

I trust that some observer with greater optical means will think it worth his time to make a special inquiry on this point. The arguments against this line indicating the spectrum of the so-called helium are absolutely overwhelming. The helium line so far has only been seen in the very hottest part of the sun which we can get at. It is there associated with *b* and with lines of iron which require the largest coil and the largest jar to bring them out, whereas it is stated to have been observed in stars where the absence of iron lines and of *b* shows that the temperature is very low. Further no trace of it was seen in Nova Cygni, and it has even been recorded in a spectrum in which C was absent.

It is even possible that the line in question merely occupies the position of D_3 by reason of the displacement of D by motion of the "stars" in the line of sight. On this point no information is at hand regarding any reference spectrum employed. If, however, it should eventually be established that the line is really D_3, which probably represents a fine form of hydrogen, it can only be suggested that the degree of fineness which is brought about by temperature in the case of the sun is brought about in the spaces between meteorites by extreme tenuity.

The Case of Nova Cygni.

The case of Nova Cygni is being discussed, and it appears likely that this "star" passed through all the stages of temperature represented by "stars" with bright lines, comets, and nebulæ. In the initial stage, the principal lines recorded were those of hydrogen, cool magnesium, and sodium. At a later date, in addition to these, lines apparently indicating hotter magnesium and carbon were observed. On the date of its highest temperature (December 8, 1876) the lines observed by Vogel indicate H, Na, Mg, C, Fe, Mn, and Ba, the "star" having then, it would appear from the discussion so far as it has yet gone, approached the condition of the great comet of 1882 at perihelion. The Fe, Ba, C, and Na gradually disappeared, then the hydrogen followed, and the last stage of all was that in which Mg (500) appeared alone, as in the comets of 1866–67 and in nebulæ. The complete discussion, however, must be reserved for a future communication. It is sufficient to say here that it is very probable that all the spectroscopic phenomena of Nova Cygni will admit of explanation on the supposition that it was produced by the collision of two swarms of meteorites. The outliers were first engaged, and at the maximum the denser parts of the swarm.

Difficulties connected with the Discussion.

An inspection of the maps, on which are shown all the observations already made upon bright lines recorded in the spectra of celestial bodies, will indicate at first sight an apparent variation of the positions of the lines greater than might have been expected. This, however, I think will vanish on the consideration of the whole question; and for my part certainly all the examinations which I have been able to make have led me to the conclusion that the various observations have been far better than it was almost possible to hope for when the great difficulties of the observations themselves are considered.

When it is remembered that, in order to get a determination of the position of a bright line, comparison-spectra and prisms are needed, and that, from mechanical considerations alone, the application of these aids to research is very frequently attended with difficulties and uncertainties; and further, when we consider that many of the observations have been necessarily made without these aids; the striking coincidences on the maps become of very much greater importance than the slight variations seen between the positions of the same line recorded by different observers in the same star.

It will be observed, too, that the information in some cases is fuller in the blue part of the spectrum. Here again a reference to what the maps are really intended to show is necessary. The maps do not show the complete spectrum observed, but only the bright lines recorded in it. The actual observations have really consisted in picking out these bright lines from the background of continuous spectrum, whether in stars, nebulæ, or comets; and, as the continuous spectrum will be generally brightest in the yellow and green, so in this part of the spectrum we must expect, first of all, to get the least information, and then, when the information is obtained, to get the greatest uncertainty, on account of the difficulty brought about by the greater luminosity of the background on which the line appears.

The discussion by Hasselberg and others of the various observations of comets which have been made from time to time indicates that under certain circumstances, where men of the highest skill and with the greatest care have determined the wave-lengths of the carbon bands, discrepancies exist too great to admit of their being attributed to errors inherent in this branch of observation.

If for a moment we consider alone the two bright flutings visible in the spectrum of carbon, one with its bright edge just more refrangible than b_4—this is the high-temperature spectrum—and the other—the low-temperature spectrum—with a fluting just less refrangible than b_1, it is at once suggested that sudden changes in comets may very likely be accompanied by a transition from one condition of carbon vapour to the other, so that on this account apparent discrepancies in the measurements of the same comet at different times may represent real facts. Then again we have the motion of the swarm along its orbit, which in some cases we know is comparable to the velocity of light, so that variations of wave-length are produced as indicated in comet 1882. We also have the possibility that the velocity of the vapours in the jets, and that due to the electric repulsion—which, according to Zöllner's view, is the origin of comets' tails—may also produce changes of refrangibility.

Although as a rule the bright fluting seen in comets appears to be that due to high temperature, this is apparently not always the case. In the experiments on the glow of magnesium wire, the flutings of carbon have always been seen, and when the vacuum is approached the flutings have been those of the low-temperature spectrum. When the glow of the metal is seen under certain conditions, mixed with carbon vapour, b_1 and b_2 are seen as bright dots or short lines inside the carbon fluting, exactly as they were observed, probably, by Huggins in Brorsen's comet (Proc. R. S., vol. xvi. p. 386).

Authorities used in the Maps.

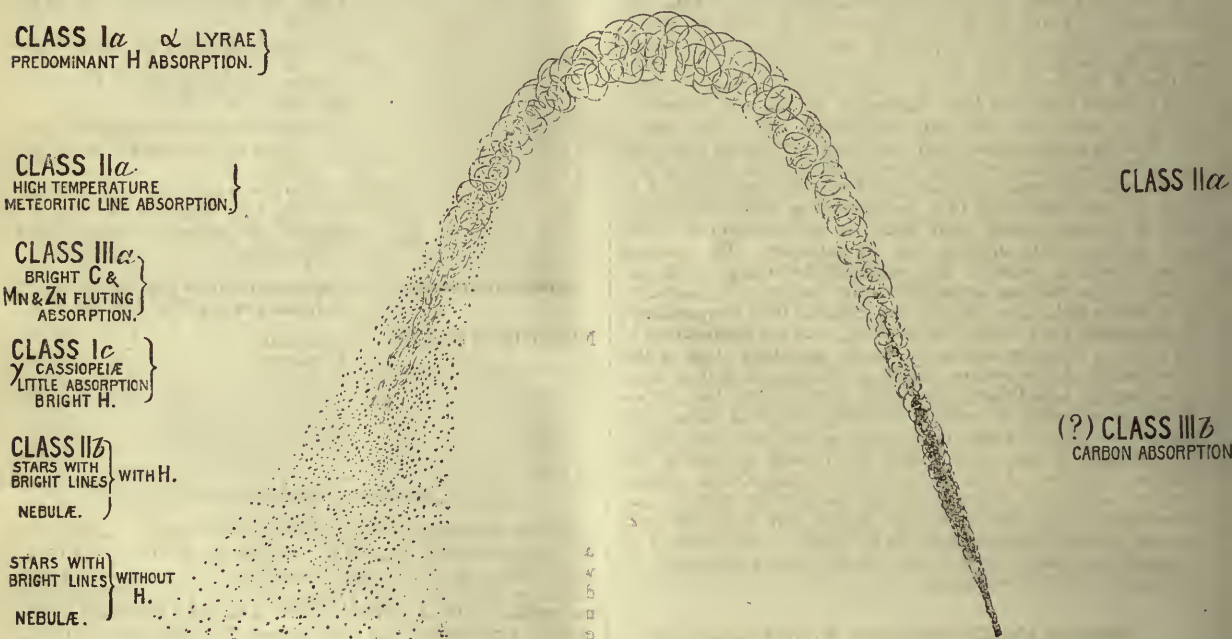
On the Absorption Phenomena of Stars with Bright Lines.

In addition to the map showing the bright lines visible in those stars the spectra of which contain them, I have prepared another map showing the absorptions which also occur. The two maps present a remarkable agreement—that is to say, there is the same progression in the absorption phenomena as there is in the bright-line phenomena. In those stars in which bright lines are seen without the lines of hydrogen (in which stars the meteorite swarm is probably at a slightly higher temperature than that observed in the nebula when only the line at 500 is visible) we have no marked absorption-lines, but rather bands. When the hydrogen lines are added, as in γ Cassiopeiæ, then we get the absorption of sodium and *b* of magnesium, as we should expect. The individual meteorites therefore are much cooler in these stars than in the Novas, seeing that the absorption is so little developed. Speaking generally, therefore, we may say that there are two causes of minimum absorption phenomena in stars. In the first place, as in the bright-line stars, only little vapour surrounds each meteorite, and that vapour consists of the substances visible at the lowest temperature; while, on the other hand, in stars like Sirius, in consequence of the absolute state of vapour, we only get practically the absorption of hydrogen, or at all events the absorption of hydrogen in great excess, due, I have very little doubt, in part, to the fact that most other substances have been dissociated by the intense heat resulting from the condensation of the meteorites.

NOTES ON THE PROVISIONAL TEMPERATURE CURVE.

In order to bring the various results referred to in this communication in a definite form before my own mind, I have prepared a diagram which I have called a temperature curve, so



Provisional Temperature Curve.

that on one side of it we may consider those stages in the various heavenly bodies in which in each case the temperature is increasing, while on the other arm of the curve we have that other condition in which we get first vaporous combination, and then ultimately the formation of a crust due to the gradual cooling of the mass. At the top of such a curve we shall of course have that condition in which the highest temperature must be assumed to exist. In a letter to M. Dumas in the year 1872, I suggested that possibly the simplification of the spectrum of a star might be associated with the highest temperature of the vapour, and that idea seems to have been accepted by other observers since that time. We shall have then stars of the first class at the top of the temperature curve. On the one arm of the curve representing increasing temperature we shall have at various heights those aggregations which give us indications of a gradually increasing temperature brought about by collisions, beginning with meteorites as widely separated as they can be to *keep up* any luminosity at all, and finally vaporous condensations due to gravity.

On the arm of the curve descending from stars of the first class to dark bodies like, say, the companion to Sirius, we must place those bodies where absorption of compound molecules is indicated. This we find in stars of Class III.*b* of Vogel. But here a very interesting question arises. Between stars of the first class and that of III.*b* we are bound to insert stars of Class II., already located naturally on the ascending arm.

The Case of Equal Temperatures on Either Side of the Curve.

Speaking roughly, it may be said that the construction of such a curve as this suggests that similar or nearly similar temperatures will be found on either side. This in the main, of course, is true; but it must be pointed out that, on the rising curve, the temperature will be that, as a rule, of individual meteorites and the vapours given out by them, while on the descending arm it will be the temperature of the consolidated mass, whether vaporous or becoming solid. But it is obvious that if we take two points near the top of the curve we shall have very nearly the same temperature of the atmosphere, by which I mean the temperature of the layers in either case which are most effective in producing the phenomena of absorption. To take a concrete case, stars of the second class are obviously, by the consent of all, of a lower temperature than stars of the first class: on which side, therefore, of the curve must they be placed? Or, to take a more concrete case still, our sun is a star of the second class: on which arm of the curve must we place the sun? Here

we find ourselves in a position of some difficulty, but it would appear that future work may enable us really to divide stars of the second class into two series, and if we can do so there is very little doubt that one series will represent the phenomenon of decreasing temperature of the absorbing layers, while the other series will represent the phenomenon of increasing temperature.

What considerations are likely to help us in such an inquiry as this? The atmosphere of a star built up by meteorites should resemble in its constitution the totality of the chemical constitution of meteorites, and therefore it might be inferred that the spectroscopic phenomena presented by such an atmosphere would not be widely different from the spectroscopic phenomena presented by the vapours of many meteorites volatilized together.

To investigate this question I have obtained composite photographs of the spectra of several meteorites, with a solar spectrum for purposes of comparison. I find that, while, on the one hand, the composite photograph giving us the spectrum of the meteorites greatly resembles that of the sun, as it should do, there are some variations which suggest the line of separation to which I have before alluded. From Dr. Huggins's magnificent photographs of the stars we have learned that, as I had predicted years before the photographs were taken, the thickness of H and K varies very greatly in different stellar spectra. In those stars, presumably the hottest ones, in which we get the series of hydrogen lines almost alone as great absorbers, K is almost absent; it finally comes in, however, and after a certain stage has been reached it is the most important line in the spectrum. But there are stars in which the lines *h* and G of hydrogen are not very much more developed than they are in the case of our own sun, in which K is much thinner than in the solar spectrum; and associated with this condition of K there is the absorption of a hydrogen line more refrangible than K at wave-length 3800, which is not represented in the solar spectrum with anything like the intensity. The question arises, therefore, whether the enormous thickening of K observed in the sun and some other stars may not be limited to those stars which, like our sun, are reducing their temperature; for we certainly are justified in assuming that the temperature of the sun now is not so high as it was in an earlier stage of the development of the system. Such a difference as that, if it is subsequently established, can only come from the atmosphere, as an effect of cooling, becoming richer in those substances the lines of which get broader as the star cools down. We can easily imagine that during the process of cooling the relative quantities of the vapours should not always remain constant, although it is impossible in the present state of our knowledge to give any particular reason why such and such vapours should disappear from the spectrum in consequence of chemical combination, while others should develop apparently in consequence of their retirement.

Hydrogen plus Carbon indicates Mixed Swarms.

If we assume a brightening of the meteor-swarm due to collision as the cause of the so-called new stars, we have good grounds for supposing that in these bodies the phenomena should be mixed, for the reason that we should have in one part of the swarm a number of collisions probably of close meteorites, while among the out-liers the collisions would be few. We shall in fact have in one part the conditions represented in Class III.*a*, and in the other such a condition as we get in γ Cassiopeiæ. I have in another part of this paper discussed the flutings observed in Nova Orionis, and have shown that so far as they were concerned we have the radiation of carbon and the absorption of manganese; but there is evidence to show that with these fluted appearances bright lines were observed—D_3 and F, although no mention is made of C.[1]

We have here, there is little doubt, the *vera causa* of stellar long-period variability. 12 per cent. of stars of Class III.*a* are variable, and 9 per cent. of Class III.*b*. In the one case, meteor-swarms produce the increased brightness by colliding with those of the condensing one. In the other, they do so by their periastron passage round the dim condensed one. There is no variability, in the usual sense of the word, in stars like the sun and α Lyræ, and the reason is now obvious.

[1] Konkoly, *Astr. Nach.* 2712, D_3 and F; Riccò indicates D_3 in *Astr. Nach.* 2707.

The Conditions of Collisions of Meteorites.

The Chemical Elements most frequently determined in Meteorites.

I think it well to give here as a reminder a short table showing the chief substances met with in meteorites. It will indicate the cause of the continued reference to the spectra of Mg, Fe, and Mn in what follows.

SIDERITES.

	Nickel-iron, copper, manganese.
	Troilite = FeS.
	Graphite.
	Schreibersite = iron and nickel phosphide.
	Daubréeite = iron and chromium sulphide.

SIDEROLITES.

CHONDRITIC—	
(α) Non-carbonaceous	= Olivine = chrysolite = peridot = $(MgFe)_2O_4Si = SiO_2$ 41·3, MgO 50·9, FeO 7·7.
	Enstatite $MgO_3Si = SiO_2$ 60, MgO 40.
	Bronzite = enstatite in which some Mg is replaced by Fe.
	Nickel-iron, manganese.
	Troilite.
	Chromite = iron protoxide 32, chromium sesquioxide 68, + Al and Mg.
	Augite = pyroxene, SiO_2 55, CaO 23, MgO 16, MnO 0·5, FeO 4.
	Silicate of calcium, sodium, and aluminium.
(β) Carbonaceous ..	... Carbon in combination with H and O.
	Sulphates of Mg, Ca, Na, and K.
NON-CHONDRITIC	= Anorthite.
	Enstatite.
	Bronzite.
	Olivine.
	Augite.
	Troilite.

The Numbers of Meteorites in Space.

It is well known that observations of falling-stars have been used to determine roughly the average number of meteorites which fall on the earth each twenty-four hours; and having this datum to determine the average distance apart between the meteorites in those parts of space which are traversed by the earth as a member of the solar system, Dr. Schmidt, of Athens, from observations made during seventeen years found that the mean hourly number of luminous meteors visible on a clear moonless night by one observer was fourteen, taking the time of observation from midnight to 1 a.m.

It has been further experimentally shown that a large group of observers who might include the whole hemisphere in their observations would see about six times as many as are visible to one eye. Prof. H. A. Newton and others have calculated that making all proper corrections the number which might be visible over the whole earth would be a little greater than 10,000 times as many as could be seen at one place. From this we gather that not less than twenty millions of luminous meteors fall upon our planet daily, each of which in a dark clear night would present us with the well-known phenomenon of a shooting-star.

This number, however, by no means represents the total number of minute meteorites that enter our atmosphere, because many entirely invisible to the naked eye are often seen in telescopes. It has been suggested that the number of meteorites if these were included would be increased at least twenty-fold: this would give us 400 millions of meteorites falling on the earth's surface daily. If we consider, however, only those visible to the naked eye, and if we assume that the absolute velocity of the meteors in space is equal to that of comets moving in parabolic orbits, Prof. H. A. Newton has shown that the average number of meteorites in the space that the earth traverses is in each volume equal to the earth about 30,000. This gives us a result

in round numbers that the meteorites are distributed each 250 miles away from its neighbours.[1]

If, then, these observations may be accepted to be good for any part of space, we may, and indeed must, expect celestial phenomenon which can be traced to meteorites in all parts of space.

Further, we have the experience of our own system that these meteors are apt to collect in groups.

A comet, it is now generally accepted, is a swarm of meteors in company. Such a swarm finally makes a continuous orbit by virtue of arrested velocities; impacts will break up large stones and will produce new vapours in some cases, which will condense into small meteoroids.

A meteorite in space under any of the conditions indicated by the comets, new stars, and such first-magnitude stars as α Orionis, will evidently be subject to collisions, but only to a greater number of collisions than those which must ordinarily occur if space is as full of meteorites as Prof. Newton's calculations, from observations made on the earth, would naturally seem to indicate.

The Velocity of Luminous Meteors.

In spite of the difficulties which attend the observations necessary to determine the velocity of meteors entering our atmosphere, many observations have been made from which it may be gathered that the velocity is rarely under 10 miles a second or over 40 or 50. It is known that the velocities of some meteor-swarms are very different from those of others. Prof. Newton, our highest authority on this subject, is prepared to consider that the average velocity may be taken to be 30 miles a second.

Result of Collisions.

If we take these velocities as representing what happens in other regions of space, and assume the specific heat of the meteorites to be ·10, the increase in their temperature when their motions are arrested by impacts will be roughly as follows:—

Velocity 1 mile per second	... ...	3,000° C.
,, 10 ,, ,,	... ...	300,000°
,, 20 ,, ,,	... ...	1,200,000°
,, 30 ,, ,,	... ...	2,700,000°
,, 60 ,, ,,	... ...	10,800,000°

It is clear, however, that we should under the conditions stated be more frequently dealing with grazes than collisions.

Comets due to Collisions of Meteorites.

The fact that comets are due to swarms of meteorites was first established by Schiaparelli in 1866, when he demonstrated that the orbit of the August meteors was identical with that of the bright comet of 1862.[2]

Nebulæ due to Collisions of Meteorites.

So far as I know the first suggestion that nebulæ were really in some manner associated with meteorites and not with masses of gas was made by Prof. Tait in 1871.[3] I have used the suggestion in my lectures ever since, and it is now some years ago since I put it to an experimental test by showing that both the spectra of comets and nebulæ, so far as carbon and hydrogen were concerned, could be produced from a vessel containing the vapours produced by meteorites. More recently, M. Faye has stated in his works on the nebular hypothesis that the solar nebula may as probably have consisted of a cloud of stones as of a mass of gas. This view, however, has not been favoured by Dr. Huggins, who in his observations both on nebulæ and comets has inferred from the near coincidence of the line of 500 with the strong air line that we are probably in presence of nitrogen, or of a form of matter more elementary than nitrogen; the line at 373 being attributed by him also to some unknown form of hydrogen on account of its coincidence with one of the series of hydrogen lines in the ultra-violet observed in the spectra of stars of the first class.

[1] Article on "Meteorites," Prof. Newton, "Encyclopædia Britannica," vol. xvi.

[2] Letters to Father Secchi, printed in the *Bollettino* of the Collegio Romano, and reproduced in *Les Mondes*, t. xiii.

[3] "It seems to me that we have a series of indications of what (for want of a better phrase) may be called the *period of life* of a star or group, beginning with the glowing gases developed by impacts of agglomerating cold masses (planetary nebulæ and others irresolvable, such as these of Orion, Lyra, &c., where the spectrum consists of a very few bright lines only)" (Prof. Tait, Proc. R.S. Edin., 1871).

"New Stars" due to Collisions of Meteorites.

The idea that the *Novas* which appear from time to time are due to collisions of meteorites was, I think, first advanced by myself in 1877, when I wrote in connection with Nova Cygni:—

"The very rapid reduction of light in the case of the new star in Cygnus was so striking that I at once wrote to Mr. Hind to ask if any change of place was observable, because it seemed obvious that, if the body which thus put on so suddenly the chromospheric spectrum were single, it might only weigh a few tons, or even hundredweights, and, being so small, might be very near us. Mr. Hind's telescope was dismounted, and I have not yet got any information as to change of position; and as I am now writing in the Highlands, away from all books, I have no opportunity of comparing the position now given by Lord Lindsay in R.A. 21h. 36m. 52s., Decl. + 42° 16′ 53″, with those given on its first appearance by Winnecke and others.

"We seem driven, then, from the idea that these phenomena are produced by the incandescence of large masses of matter, because if they were so produced, the running down of brilliancy would be exceeding slow.

"Let us consider the case, then, on the supposition of small masses of matter. Where are we to find them? The answer is easy: in those small meteoric masses which, an ever-increasing mass of evidence tends to show, occupy all the realms of space."[1]

The Effects of Collisions.

The question of what must happen to the meteorites themselves in consequence of this system of collisions is worth going into thoroughly. A very cursory examination seems to indicate that much light is thrown on the condition of meteorites as we know them, and their division into iron and stony.

As 30 miles per second is a very frequent value obtained for the velocity of meteorites when they enter our atmosphere, it is possible to compare temperatures brought about by collisions with those produced by passage through our atmosphere. Two masses of meteoric iron meeting each other in space would probably, if moving with a certain velocity, be formed into a pasty conjoined mass, and this process might go on until an iron of large dimensions was formed, and the various meteorites thus welded together would present in time a very fragmentary appearance. While irons were thus increasing in size, collisions with smaller meteorites would be attended with very local increases of temperature, perhaps sufficient to volatilize the surface or allow it to be indented, and in this manner the well-known "thumb-marks" receive explanation.

The masses of iron, when in a state of fusion, whatever their size, would be able to include stony meteorites in their vicinity. In the case of stones it is easy to see that the result would be very different. Their collisions would have, most probably, the effect of reducing large pre-existing masses to smaller ones, and the collision of a large stone with a large iron would probably effect the driving of the stone into fragments, while the iron would be liquefied so as to inclose some of the fragments in its mass.

These operations of Nature might go on either in free space, or in the head of a comet, or in meteor-swarms. They probably cause the appearance of the so-called new stars, and in these various circumstances the rate of subsequent cooling would of course be very different, so that the results would be very different indeed.

Large masses on collision probably destroy each other, produce fragments and vapour, which again condense. The heterogeneous structure is thus to a certain extent explained. On collision the part of the substance of the meteorite given up will depend on the temperature, and thus a mass of metallic iron mixed with silicates at low temperature will get rid of the iron at once, which must then perforce condense in a separate swarm; therefore under low temperature conditions, say at aphelion, irons alone will be formed and the stones will become spongy. The stones will absorb the C and H vapours.

[1] NATURE, vol. xvi. p. 413.

I have finally to express my great obligations to Messrs. Fowler, Taylor, and Richards, who have helped me in various ways in the researches embodied in this paper. Mr. Fowler, the assistant to the Solar Physics Committee, has made most of the observations on meteorites, and low-temperature spectra generally, which have been recorded on the maps, and he has carried out this work with a care, skill, and patience beyond all praise. The observations have in nearly every case been checked also by myself. Mr. Taylor, the Demonstrator of Astronomy, has been chiefly responsible for looking up the literature and mapping the results, in which he has been aided by Mr. Richards.

J. NORMAN LOCKYER.

SIR JULIUS VON HAAST, F.R.S.

SCIENCE in Australasia, and especially in New Zealand, has recently sustained a great loss by the death, on August 16 last, of Sir Julius von Haast. He was born on May 1, 1824, at Bonn, where his father was a wealthy merchant. After passing through the grammar-schools of Bonn and Cologne, he entered the University of Bonn, and devoted a considerable portion of his time to geological and mineralogical studies. He then spent some years in France, and made journeys for the purpose of scientific exploration in Russia, Austria, and Italy. Being invited by an English firm of ship-owners to visit New Zealand on their behalf in order to report upon its fitness as a field for German emigration, he went to London, and accepted their offer after some negotiation; and on December 21, 1858, he arrived at Auckland. The next day, by a lucky chance, the Austrian ship *Novara*—then on its voyage of scientific research—put into Auckland; and when Dr. von Hochstetter was left behind, at the request of the New Zealand Government, he took Mr. Haast as his lieutenant and companion in all his journeys in these islands. After the departure of Hochstetter, Mr. Haast was engaged by the Provincial Government of Nelson to explore the west coast of the province, and in the journey undertaken in the pursuit of these duties he commenced his examination of the physical geography and geology of the Southern Alps. The results of the exploration were published in a report printed by the Nelson Government and dated January 1, 1861.

Immediately after the conclusion of the Nelson journey—namely, in December 1860—he undertook to report to the Government of the Province of Canterbury as to the possibility of constructing a tunnel through the hills which separate Christchurch from its port of Lyttelton; and in the following year he was appointed to the command of the Geological Survey of Canterbury, being thus the first Government geologist in New Zealand. It was in this capacity that he accomplished the most valuable part of his scientific work. The most striking of his achievements were the examination of the Mount Cook district; the sketching and mapping out of the great glaciers of the Southern Alps, named by him the Tasman, Franz Joseph, Hochstetter, Hooker, and Müller glaciers, and many others; and the forecast and subsequent examination made of the auriferous districts of Westland. All this, with the geographical, zoological, botanical, and meteorological researches carried on side by side with the more exclusively geological work, was in continuation of what had been done in the Nelson or northern portion of the same mountain system. The results of his investigations were set forth in the chief book published by him—namely, "The Geology of Canterbury and Westland." He was also the author of many papers in scientific periodicals.

Last year he acted as New Zealand Commissioner at the Indian and Colonial Exhibition. Afterwards he visited Paris, Brussels, Berlin, Dresden, Vienna, Halle, Venice, Florence, and other centres, obtaining a vast number of things for the Canterbury Museum, the flourishing condition of which is mainly due to his energy and zeal. His labour in connection with the Exhibition, and the subsequent wear and tear of travelling while in weak health, appear to have overtaxed his strength, and he died of heart-disease a month after his return to New Zealand.

NOTES.

THE fourth session of the International Geological Congress will be held next year in London. The Congress was founded at a meeting of the American Association for the Advancement of Science at Buffalo in 1876, the first session being held at Paris in 1878, the second at Bologna in 1881, the third at Berlin in 1885. The following is a list of the Organizing Committee appointed to carry out the arrangements:—H. Bauerman, W. T. Blanford, F.R.S., Rev. Prof. T. G. Bonney, F.R.S., Prof. W. Boyd Dawkins, F.R.S., John Evans, F.R.S., Prof. W. H. Flower, F.R.S., Arch. Geikie, F.R.S., Prof. James Geikie, F.R.S., Sir Douglas Galton, F.R.S., Prof. A. H. Green, F.R.S., Rev. Prof. S. Haughton, F.R.S., Prof. T. H. Huxley, F.R.S., W. H. Hudleston, F.R.S., Prof. T. McK. Hughes, J. W. Hulke, F.R.S., Prof. E. Hull, F.R.S., Prof. J. W. Judd, F.R.S., Prof. J. Prestwich, F.R.S., F. W. Rudler, H. C. Sorby, F.R.S., Sir W. W. Smyth, F.R.S., W. Topley, Rev. Prof. Wiltshire, Henry Woodward, F.R.S. The duty of this Committee will be to nominate the officers, to appoint Executive Committees, and to fix the exact date of meeting. The Congress at Berlin requested that the meeting should be held in London between August 15 and September 15.

DR. DAWSON, Assistant-Director of the Canadian Geological Survey, who headed the party sent by the Dominion Government to explore the country adjacent to the Alaska boundary, has returned to Victoria. Two of his party, Messrs. Ogilvie and McConnell, will winter in the district, preparing the way for the establishment of the international boundary. The Expedition so far has secured a great deal of geological, geographical, and general information about the country, which is far from being the Arctic region it is sometimes represented to be. The point from which Dr. Dawson turned back was at the junction of the Lewis and Pelly Rivers. It is 1000 miles north of Victoria. There the flora was found to differ but little from that on the banks of the Fraser. A great deal of open grassy country exists along the stream's tributary to the Yukon. No areas of tundra or frozen swamps, such as are to be met with in the interior of Alaska, were discovered by the Expedition. Dr. Dawson's conclusion is that the whole country, from Cassiar to the vicinity of Forty-mile Creek on the Yukon River (which must be near the eastern boundary of Alaska), yields more or less gold in placer deposits. This would constitute a gold-bearing region fully 500 miles in length, and of indefinite width.

AT a meeting of the Council of University College, Bristol, held on Wednesday, November 16, it was decided, at the suggestion of the staff of the College, to suspend for a year the office of Principal. Prof. Lloyd Morgan was in the meantime appointed academical head of the College, and Chairman of the Educational Board, with the title of Dean.

AT the Royal Institution, Sir Robert Stawell Ball, the Astronomer-Royal of Ireland, will give a course of six lectures (adapted to a juvenile auditory) on Astronomy: the Sun, Moon, Planets, Comets, and Stars. The course will begin on December 27. Courses of lectures will also probably be given by Lord Rayleigh (Professor of Natural Philosophy at the Royal Institution), Dr. G. J. Romanes, Mr. Hubert Herkomer, Prof. C. Hubert H. Parry, the Rev. W. H. Dallinger, and Mr. William Archer.

WE are requested to state that the lectures to be given on behalf of the Anthropological Institute by Mr. Francis Galton—which were postponed in consequence of that gentleman's indisposition—will be delivered in the Lecture Theatre of the South Kensington Museum on Saturday, the 26th inst., and the two following Saturdays, December 3 and 10.

AN International Exhibition will shortly be held by the Ornithological Society at Berlin.

A MAGNETIC Observatory is about to be erected near the Solar Observatory, on the Brauhausberg, near Potsdam.

A CORRESPONDENT writes to us from Venice that on the 9th inst. an earthquake occurred there at 1.32 a.m. There were five gentle undulations, which lasted ten seconds. On the same morning—at 1.30 a.m.—a shock at Ferrara is said to have lasted seven seconds.

THE other day Mr. Ruskin sent to the *Times* the following extract from a letter, dated November 14, which he had received from a friend at Florence:—"We had an earthquake this morning, which frightened everybody, and my door shook so that I thought somebody was trying to break in, and then there was a terrible noise, but I believe no harm done. The bells rang of themselves at the Carmine, and some say that one or two chimneys fell, but nobody seems to know." From a report issued by Signor Passerini, Director of the Meteorological Observatory connected with the Agricultural College of Scandicci, we learn that three shocks were felt there on the 14th, the first taking place about 5.20 a.m. It was accompanied by a rather loud rumbling, and was powerful enough to shake all the furniture in Signor Passerini's room. A second shock, weaker, and not accompanied by rumbling, was felt about twenty minutes later. At 6.49 a.m. the third shock, the strongest of all, and accompanied by loud rumbling, was felt. During the continuance of this shock people in the open country saw trees much shaken, and quantities of leaves were observed to fall. The direction of the shocks was from north-north-west to south-south-east.

AT the suggestion of Prof. Mushketoff, who has just returned from his official visit to Semiretchia, a special Commission has been appointed to watch the course of any earthquakes that may happen, and to report on them, in those parts of the Russian Empire which are most frequently visited, such as the Caucasus, Turkestan, and the Transbaikal region.

ADVICES from Baku state that a naphtha spring has burst forth near the town of Balachany, the oil being thrown to a height of over 100 feet and carried away long distances by the wind. Sometimes the oil falls like rain over the adjacent districts, and forms small streams, whilst heavy naphtha gases fill the air.

ANOTHER contribution to the subject of photography in colours is published by Mr. Carey Lea in the November number of the *American Journal of Science*. Although the interpretations placed upon his former experiments have not received universal acceptance in this country, still the experiments themselves have been generally received with considerable interest and surprise, and indeed are at the present time being repeated and considerably extended in more than one English laboratory. The appearance of another communication from Mr. Carey Lea is therefore most opportune, and will doubtless form the subject for considerable discussion. It will be remembered that the so-called photo-salts of silver, a description of which appeared in these columns a few months ago, were said to consist of combinations of ordinary chloride of silver with small quantities of subchloride. Mr. Carey Lea now finds that silver chloride combines with small quantities of many other chlorides, besides its own subchloride, to form coloured salts, comparatively stable and remarkably less sensitive to light. Thus if silver nitrate be added to a solution of ferric chloride in presence of free hydrochloric acid, the precipitate obtained is buff-coloured, and the ferric chloride carried down by the silver chloride cannot be washed out even by hydrochloric acid. The most remarkable property of this silver-ferric chloride is that it is almost unacted upon by light. Chlorides of cobalt, nickel, manganese, and mercury give analogous combinations, each having a characteristic colour. As those chlorides, such as ferric and mercuric, which readily part with one equivalent of chlorine, act most energetically in reducing the sensitiveness, it appears probable that the traces of chlorine thus capable of being given up, simply hold in check the commencement of the movement towards reduction.

WE have received from Mr. Stewart Culin the reprint of a paper read by him before the Anthropological Section of the American Association at its meeting at New York during the past autumn. It is entitled "China in America: a Study in the Social Life of the Chinese in the Eastern Cities of the United States," and describes the special districts in Southern China from which the immigrants mostly come, the guilds and associations they form, their mode of life, their pleasures, which are somewhat few and simple, and much else in respect to them that is of a very interesting character. His own contact with the Chinese in the United States leads him to form a favourable estimate of their character and attainments, which have been the subjects of much misconception. They are not "the dregs of the people, given up to gambling and opium-smoking, and distinguished only by their vices," as the anti-Chinese orators aver; nor are their mental and moral qualities quite so high as others allege. But we fear very much that Mr. Culin is over sanguine in the anticipation that the returning emigrants will some day carry enlightenment to their own country. Their work is not of a kind that enables them to acquire very great knowledge of the resources of the West; they come with a special object, viz. the acquisition of a competence, they toil unremittingly until that is attained, when they speed home again, usually with no very pleasant memories of the land of their sojourn. To China herself we must look for the elements of her regeneration, and time, which is the great solvent, will have its slow effect on that huge mass of humanity.

THE German publisher, Herr Trewendt, of Breslau, has just issued the twentieth part of a Dictionary of Zoology, Anthropology, and Ethnology; the twenty-fourth and twenty-fifth parts of a Dictionary of Chemistry; and the twentieth part of a hand-book of Botany. These works belong to the elaborate "Encyklopædie der Wissenschaften," edited by Dr. W. Förster, Dr. A. Kenngott, Dr. A. Ladenburg, and other scientific writers.

PROF. FOREL is at present studying the penetration of light into the Lake of Geneva, by means of the photographic effect on chloride of silver paper. Six photographic apparatus are attached one above another to a rope at 10-metre intervals. They are let down into the lake after sunset, left there one day or more, and taken up again at night. The depth-limit of absolute darkness has been found this year, in the beginning of March, 100 m.; of May, 75 m.; and of July, 45 m. Prof. Forel hopes to carry on these experiments for a whole year, every two months, and so obtain the curve for penetration of light into the lake.

THE loss of electricity by a conductor in moist air has been lately studied by Signor Guglielmo (Turin Academy). He finds that with potentials less than 600 volts, moist air insulates as well as dry air, but with higher potentials, there is more loss in moist air, and more the moister the air, and the higher the potential. The potential at which the difference becomes per-

ceptible is the same for a ball as for a fine point. It occurs with extremely smooth surfaces, and so cannot be attributed to discharges in consequence of roughness of surface. With equal potential the loss of electricity has the same magnitude, whatever the dimensions of the balls used as conductors. In air saturated with vapours of insulating substances, the loss of electricity of a conductor is nearly the same as in dry air.

THE large Russian ironclad *Tchesme*, now being finished at Sebastopol, and having a displacement of over 10,000 tons, is to have boilers heated with petroleum. If the results correspond to what the Sebastopol engineers expect, the example is likely to be followed elsewhere. In this connection we may note an account in *La Nature* of November 5, of a gas-boat, as it may be called, the *Volapuk*, recently constructed by M. Forest, in which a gas-engine of six horse-power is driven, not by coal-gas, but by air charged with carbureted hydrogen, by passage through petroleum-oil. There are two pistons, and the explosive mixture is ignited by means of a spark from a magneto-electric arrangement. The engine consumes six litres of petroleum-oil per hour, giving a speed of sixteen kilometres per hour.

AMONG the various uses of celluloid, it would appear (according to the *Annales Industrielles*) to be a suitable sheathing for ships, in place of copper. A French Company now undertakes to supply the substance for this at 9 francs per surface-metre and per millimetre of thickness. In experiments by M. Butaine, plates of celluloid applied to various vessels in January last were removed five or six months after, and found quite intact and free from marine vegetation, which was abundant on parts uncovered. The colour of the substance is indestructible; the thickness may be reduced to 0·0003 metre; and the qualities of elasticity, solidity, impermeability, resistance to chemical action, &c., are all in favour of this use of celluloid.

THE following interesting observations with regard to the mobility of loess have been made by M. Potanin during his last journey through the region south of the Ordos. As wind steadily moves the shifting sands, so also water steadily moves the loess, transporting it from higher to lower levels. The underground water which filtrates through the loess, begins by making in it a kind of cavern; then a circular crevice appears on the surface over the cavern, and a cylindrical vertical hollow, which soon becomes a deep well, is formed through the thickness of the upper layers of the loess. The whole surface of the loess deposits is dotted with such wells, very dangerous to cattle. By and by the formerly cylindrical well begins to extend in the direction in which the underground water flows, and a narrow ravine grows until it joins the main valley. Then masses of loess continually fall down into the ravine, increasing its width. The fall of these masses is favoured by the numerous crevices in the loess, and it is so frequent that natives warn foreigners not to approach the borders of a ravine. Of course the fallen masses are further dislocated by water, and the loess is thus steadily transported at a remarkable speed to lower levels.

HITHERTO it has been generally supposed that the glaciers of the Caucasus are far from having the same development as those of the Alps. It appears, however, from the last researches of Abich, that, although no glaciers of the Caucasus are as long as the Aletsch and Unteraar glaciers, or the Mer de Glace, there are a great many of them. From tables compiled by M. Smirnoff in a recent issue of the *Bulletin* of the Moscow Naturalists' Society, it appears that the average lowest levels of the Caucasus glaciers are: 2504 metres in the Elburz Chain; 2176 metres in the chain to the west of the Adai-kokh; 2266 metres in the high valley of the Ingur; 2898 metres on the eastern slope, and 2238 on the northern slope, of the Kazbek; from 2428 to 2658 metres in Daghestan; 2776 metres on the Great Ararat; and as much as from 3162 to 3194 metres on the Shah-dagh. Comparing these heights with those reached by the lower extremities of glaciers in other highlands, M. Smirnoff concludes that in the main Caucasus ridge the altitudes of the snow-line and the glaciers are intermediate between the corresponding altitudes in the Alps and those in the chains of Central Asia (Thian Shan and Hindu Kush); and that in the western parts of the Caucasus the altitudes of the perennial snow-line are nearer to those of the Austrian Alps. There is some analogy between West Caucasus and the Himalayas, inasmuch as the lowest limits of perennial snow in both chains are higher on the northern slope than on the southern.

A "PANORAMA-BIJOU" (or toy panorama), has been recently brought before the French Société d'Encouragement, by M. Benoist. It is meant to give a succession of connected views of photographed scenery, &c. Externally the instrument appears as a cylindrical case with a handle projecting from its curved surface. The observer looks through a lens, in the axis, towards a mirror inclined 45°, which reflects a panoramic view fixed round the interior of an inner cylinder which is rotated by clockwork. The back of the case is of ground glass, admitting diffuse light. The instrument may be found a suitable companion to the stereoscope on the drawing-room table.

FROZEN fish are now imported into France, and a Society formed in Marseilles for the purpose of developing the trade (the Société du Trident) has a steamer and a sailing-vessel engaged in it. The steamer *Rokelle* lately came into Marseilles with some 30,000 kilogrammes of frozen fish in its hold, the temperature of which is kept at 17° C. below zero by means of a Pictet machine (evaporating sulphurous acid). The fish are caught with the net in various parts of the Mediterranean and Atlantic. After arrival they are despatched by night in a cold chamber. Experiment has shown that fish can be kept seven or eight months at low temperature without the least alteration. These fish are wrapped in straw or marine Algæ, and have been sent on to Paris, and even to Switzerland.

AT the establishment of the National Fish-Culture Association, Delaford Park, the American char, *S. fontinalis*, spawned as early as October 15. The thriving capacity of these beautiful fish is becoming yearly more and more marked. Their rate of growth at Delaford has been extraordinarily rapid.

DR. R. BALTZER, Professor of Mathematics at Giessen University, died at Giessen on November 7. He was born January 27, 1818.

ON October 22 a monument to Prof. Oswald Heer was unveiled in the Zürich Botanical Gardens. The bust of the great Swiss naturalist has been executed in a masterly manner by Prof. Hoerbst.

THE additions to the Zoological Society's Gardens during the past week include fifty-nine Pleurodele Newts (*Molge walti*), seven Marbled Newts (*Molge marmorata*) from Spain, presented by the Lord Lilford, F.Z.S.; two Moufflons (*Ovis musimon* ♂ ♀) from Sardinia, two Barbary Wild Sheep (*Ovis tragelaphus* ♂ ♀) from North Africa, two South American Flamingoes (*Phœnicopterus ignipalliatus*) from South America, deposited; ten Silky Bower Birds (*Ptilonorhynchus violaceus*) from New South Wales, eight received in exchange, and two deposited; an African Wild Ass (*Equus tæniopus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

AMERICAN OBSERVATORIES.—It is reported that the Dearborn Observatory of the Chicago Astronomical Society is to be removed to Evanston, Ill., the North-Western University at Evanston having made an advantageous offer with respect to it. A large astronomical Observatory is proposed to be erected in connection with the Lake Forest University, Governor Ross,

President of the Board of Trustees of the University, having guaranteed the cost. A new Observatory has been established at Smith College, Northampton, Mass., and Miss Mary E. Byrd, formerly assistant at Carleton College Observatory, has been appointed Director. The equipment of the Observatory at Carleton College, Northfield, Minn., is proceeding rapidly, the new meridian-circle by Repsold is already erected, and one of the two large steel domes is in place. The telescope it is to cover, an $8\frac{1}{4}$-inch refractor by Alvan Clark, will, it is expected, be ready for use within a few days. Mr. Grinnell, the founder of Grinnell, Iowa, has furnished funds for the erection of an Observatory to be attached to the Iowa College, and the building is being rapidly brought to completion. The new Observatory is to have an 8-inch equatorial by the Clarks. Prof. Asaph Hall is to act as the Consulting Director of the Washburn Observatory, whilst Prof. George Comstock will have the more immediate superintendence of the institution as Associate Director.

U Ophiuchi.—Mr. S. C. Chandler gives, in No. 162 of *Gould's Astronomical Journal*, an investigation of the light-curve of this well-known Algol-type variable, the result of which seems to indicate a curious but well-marked retardation in the increase of brilliancy some half-hour or so after minimum is passed. A similar irregularity has been noticed in the light-curve of S Cancri, and occasionally in that of Algol. It is clearly of great importance to ascertain whether this is merely subjective, due to some habit of observation, or a real peculiarity of the star itself. If the latter, it would throw considerable doubt on the satellite theory, which at present seems on the whole the most plausible explanation of variability of the Algol type.

The New Algol Variables.—Mr. Chandler also gives an ephemeris for the minima of the two new Algol-type variables, viz. R Canis Majoris, R.A. 7h. 14·3m., Decl. 16° 11′ S., and Y Cygni, R.A. 20h. 46·6m., Decl. 34° 10′ N., as follows:— Y Cygni, Nov. 26, 22h. 42·5m.; Nov. 29, 22h. 36·1m.; Dec. 2, 22h. 29·7m. R Canis Majoris, Nov. 29, 18h. 48·3m.; Nov. 30, 22h. 4·2m.; Dec. 2, 1h. 20·1m. Greenwich civil time, reckoning from midnight to midnight.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 *NOVEMBER* 27—*DECEMBER* 3.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on November 27

GEOGRAPHICAL NOTES.

At the International Exhibition to be held at Brussels next year, a special Section will be devoted to topography, cosmography, geography, and the related sciences. The following are the classes of objects desired for contribution to the Section:—(1) Maps and atlases, topographical, geographical, geological, hydrographical, astronomical, &c.; (2) physical maps of all kinds, plans in relief, terrestrial and celestial globes and spheres; (3) statistical works and diagrams, tables and ephemerides for the use of astronomers and navigators; (4) general, historical, and classical works; (5) instruments, aide-memoires, and articles of equipment for explorers. Among the "desiderata" are the following:—(1) The best map of the Congo, showing the most recent discoveries; (2) the best national map of any country; (3) utilization of the sheets of a topographical map for the preparation of special maps on the same or a different scale; (4) the execution of relief-maps; (5) transference of relief to a plane surface; (6) construction of an apparatus suitable to demonstrate by experiments the various geographical features which may be presented by a river, such as torrents, lakes, cataracts, and rapids, erosions and alluvial accumulations, subterranean streams, islands, and backwaters, freezing and breaking up of ice, floods, deltas, bars, &c.; (7) construction of a tellurium; (8) portable equipment for an explorer; (9) statistical atlases and globes. The Secretary of the Section is Prof. Du Fief, 22 Rue des Palais, Brussels.

In the *Verhandlungen* of the Berlin Geographical Society, No. 8, Dr. Mense describes in some detail a journey up the Kwango, the great southern tributary of the Congo, which he made last December in company with the Rev. G. Grenfell. It contains a good deal of local information.

The November number of the *Alpine Journal* contains Mr. D. Freshfield's diary during his recent visit to the Caucasus, when he ascended some of the highest peaks, and visited some of the principal glaciers. The diary itself and the many excellent illustrations of the peaks and glaciers visited will be found to afford useful geographical information.

At the last meeting of the Paris Geographical Society, Dr. Verneau described the results of his recent missions to the Canary Islands. His special aim was to work out the ethnology of the islands, and for that purpose he has collected many skulls and bones from caves and graves, and made many observations on the present inhabitants. The Guanches he professes to recognize as the direct descendants of a people the type of which is exhibited in the famous prehistoric Cro-Magnon skull—the troglodytes of the Vézère. He maintains that about the end of the Quaternary there must have been a great migration of what he calls the "Cro-Magnon" race from the north to the south, and a section of the migrants found their way to the Canaries. After a lapse of time these were invaded by Numidians and Semites from the north of Africa, people of a superior type and more advanced culture to the Guanches, who were troglodytes. Dr. Verneau has made many collections of anthropological interest from the Canaries, and these are likely to be of much more service to science than his theories.

METEOROLOGICAL NOTES.

MR. H. ALLEN has contributed an article to the *American Meteorological Journal* for October, on the behaviour of pressure and temperature in low and high pressure systems. Recent investigations by M. Dechevrens (and others) tend to show that, while a high temperature accompanies a low pressure at sea-level, the fluctuations are reversed at some height above sea-level. Mr. Allen maintains that this conclusion is not supported by his examination of observations made on Mount Washington, where the minimum pressure does not coincide with the passage of the storm centre over the station, but lags about eleven hours behind it, and he considers that this fact explains the peculiar results obtained by M. Dechevrens. The same number also contains an article by Prof. F. Waldo, "On the Absolute Reduction of Wind Observations at Sea." He recommends the use of some instrument to assist the judgment of different observers, at the actual time of observation.

THE results of meteorological observations made at the Radcliffe Observatory, Oxford, in the year 1884, contain daily means of eye observations and of the self-recording instruments, comparisons of the mean monthly temperatures at 5 and 105 feet above the ground, and rainfall observations on the ground at 22 and 112 feet. Interesting tables are given showing the relations of pressure, temperature, &c., under different winds. The total sunshine during 1884 was 1260·9 hours, being 173·7 hours less than the mean of five years. The observations are reckoned for astronomical and for Greenwich mean time.

ON September 19, 1887, the Russian Government gave notice that storm signals (consisting of day and night signals) would be made at their principal ports in the Black Sea. The signals are shown for forty-eight hours, unless instructions are received to lower them before that time has elapsed: also, the cause assigned for hoisting each signal will be posted up at the respective signal stations. The day signals consist of a cone, hoisted either alone, or with a drum, both painted black, and each about 3 feet in diameter. The night signals consist of three *red* lights, hoisted at the angles of an equilateral triangle, of the same size as the cone used by day. These signals correspond to those in this country—except that the drum is not now used, and night signals are only exhibited at very few stations.

IN *La Nature* of November 12 M. Jules Girard contributes an article entitled "The Probable Temperature of the Pole," based upon the results of the circumpolar expeditions of 1882–83, and upon the observations of some earlier expeditions, in which he has tabulated the mean temperatures for each month. From these data the author traces two principal centres of intense cold, one in the north of Siberia near the mouths of the Lena, and the other to the north of Hudson's Bay, near Boothia. The lowest mean temperature quoted for July is 30° at Jeannette Island, to the north of the islands of New Siberia, and the lowest mean for January is − 49° at Fort Yukon, Alaska.

THE BRITISH ASSOCIATION AND LOCAL SOCIETIES.

THE third Annual Conference of Delegates of Corresponding Societies was held at Manchester, thirty-two of these affiliated Societies having nominated Delegates to attend the meeting. The following Report of the Conference, signed by Mr. Francis Galton as Chairman, and by Prof. R. Meldola as Secretary, has just been issued:—

At the first meeting of the Conference the chair was taken by Prof. W. Boyd Dawkins, F.R.S., the Corresponding Societies Committee being represented by Dr. J. G. Garson and Prof. R. Meldola, F.R.S., Secretary.

The Chairman, in opening the proceedings, stated that the British Association was anxious to be brought into as close a relationship as possible with the local Societies of this country. The work carried on by many of these Societies was of the greatest value to science, and it was felt that their efforts might be promoted by simplifying and unifying their labours. The present meeting was called for this purpose, and for that of bringing together the representatives of the various Corresponding Societies.

The Secretary read the Report of the Corresponding Societies Committee which had been presented to the General Committee of the Association at the meeting on Wednesday, August 31.

The names of the Delegates who desired to be attached to the Sectional Committees as "Delegate Members" were collected by the Secretary in accordance with the resolution passed at the Conference last year at Birmingham (see last Report, NATURE, vol. xxxv. p. 78).

The Chairman called upon the Delegates to make any statements respecting the action that had been taken by their Societies with reference to the suggestions put forward last year, and which had been embodied in the Report just read.

Prehistoric Remains Committee.—Mr. J. W. Davis stated that the Prehistoric Remains Committee had been carrying on their work during the past year, and they proposed to apply for reappointment. Two reports had already been obtained relating to the bronze implements of the East and West Ridings of Yorkshire, and several others had been promised for next year.

Preservation of Stonehenge.—With reference to the preservation of Stonehenge, Dr. Garson stated that the resolution which had been submitted last year to the Delegates at the Birmingham Conference had been considered by the Committee of Section H, and, having been adopted by them, had been brought before the General Committee, and also accepted. He believed that in consequence of this action negotiations were now going on between the Council of the British Association and the proprietor of these remains.[1]

Prof. Boyd Dawkins remarked that the state of neglect into which Stonehenge had been allowed to fall had by no means been overstated in the resolution referred to. A person had recently been seen on a ladder chipping off pieces from the horizontal stone of one of the trilithons.

Ancient Monuments Act.—The Chairman and Dr. Garson made some remarks in explanation of the working of the Ancient Monuments Act. It was pointed out by the latter that the local Societies could do good service by inducing the proprietors of prehistoric remains to communicate with General Pitt-Rivers, the Inspector of Ancient Monuments, with the object of placing these remains under Government protection. The Chairman urged those Delegates who represented the Northern, and especially the Scotch Societies to use their influence in inducing the owners of ancient remains to assist in carrying out the objects of the Act. In reply to a question by Mr. F. T. Mott, as to whether camps and earthworks were to be taken into consideration, the Chairman did not think that any Government could be expected to become a landowner to the extent of all the earthworks in the country.

Provincial Museums Committee.—With reference to the work of this Committee, Mr. F. T. Mott stated that they had been engaged during the past year in collecting particulars respecting museums other than those in London. Considerable assistance had been given by the Secretaries of many of the local Societies. If the Committee was reappointed, as he hoped it would be, he thought there were one or two matters on which the local Societies might possibly render still more valuable aid. The Report of the Committee was not yet passed, but it would, no doubt, be read in the course of the present meeting of the Association, and would then be accessible.

Prof. Boyd Dawkins stated that the schedule issued by this Committee was a very difficult one to fill up, and he expressed a hope that something shorter and simpler would be sent out.

The Rev. H. Winwood expressed similar views.

Mr. Robert Pullar and Mr. J. W. Davis mentioned two museums which the Committee had not heard of—viz. that of the Perthshire Society of Natural Science at Perth, and Mr. Davis's museum at Chevinedge, Halifax.

Earth Tremors.—Prof. Lebour stated that the subject of earth tremors, which he had brought forward at the Conference of Delegates last year at Birmingham, had since taken a more

[1] The following extract relating to this matter is from the Council Report for 1886–87, presented at the Manchester meeting:—

"That the Council be requested to consider the advisability of calling the attention of the proprietor of Stonehenge to the danger in which several of the stones are at the present time from the burrowing of rabbits, and also to the desirability of removing the wooden props which support the horizontal stone of one of the trilithons; and in view of the great value of Stonehenge as an ancient national monument, to express the hope of the Association that some steps will be taken to remedy these sources of danger to the stones."

The Council have carefully considered the question, and, having had the advantage of perusing the detailed report recently prepared by a deputation of the Wilts Archæological and Natural History Society on the condition of the whole of the stones constituting Stonehenge, are of opinion that the proprietor should be approached with the expression of a hope that he will direct such steps to be taken as shall effectually prevent further damage.

practical shape, and that it now seemed to be time that a Committee of the British Association should be formed for taking the investigation in hand. Through the advocacy of Mr. Symons, who was unable to be present at the Conference, Sections A and G had that morning agreed to recommend the appointment of such a Committee in conjunction with Section C, which Section would be approached next day. The work to be done was of a preliminary character, and its object was rather to inquire into the best methods of conducting observations on earth tremors than to actually cause such observations to be made. The North of England Institute of Mining and Mechanical Engineers had, since the Birmingham meeting, carried on a series of seismoscopic observations at Marsden in the county of Durham; and the daily results, extending over several months and compared with a barometric curve, were shown to the meeting in the form of a diagram by Mr. Walton Brown, the Secretary of the Newcastle Institute Committee. The Institute possessed also a more elaborate instrument, made after a pattern supplied by Prof. Ewing, which registered the intensity and direction of the tremors. Prof. Lebour stated that, although such instruments as the last mentioned were probably too costly to be placed at all desirable stations, this would not be the case with the simpler seismoscope, which recorded merely the fact of earth tremors having taken place and the time of their occurrence. Such records would be valuable, though limited. The Corresponding Societies, if they would interest themselves in the matter, might be the means of establishing a great network of seismoscopes with a few seismographs in suitable localities, and results of value would by this means be in all probability obtained. These results would be valuable altogether in proportion as well-equipped seismometrical observing stations were numerous. The expense must in any case be considerable in the aggregate, but need not be great in individual cases. A sufficiently good seismoscope might be had for about £2, a seismograph for £14 to £15, and the cost of keeping them in order would not be great. Prof. Lebour hoped the Delegates present would help in establishing such a network of observing stations all over the country, and he stated, in concluding, that he would be happy to communicate with anyone interested in the subject.

Prof. Ewing, in response to the Chairman, said that from his experience of earth-tremor observations in Japan he could concur in the remarks of Prof. Lebour. To investigate fully the character of the motion, even at one station, required delicate and costly apparatus, and the cost was greatly increased when it was attempted to bring a number of stations into correspondence so as to determine the motion over a large area. It was possible, however, to record the fact that a tremor had occurred, and even to learn something of its character by means of inexpensive seismoscopes; and it certainly seemed to him that no bodies could more appropriately undertake that work than the local Societies represented at the Conference acting in conjunction with a Committee of the Association. From recent observations it appeared probable that tremors would be found wherever they were tested for with sufficient delicacy, so that a Society undertaking the search was not likely to be disappointed.

At the second Conference the chair was taken by Prof. Boyd Dawkins, F.R.S., who was succeeded by Mr. W. Topley, the Corresponding Societies Committee being further represented by Mr. G. J. Symons, F.R.S., Dr. Garson, Mr. William White, and Prof. R. Meldola, F.R.S., as Secretary.

The Chairman invited discussion on the recommendations received from the various Sections.

Section A.

Temperature Variation in Lakes, Rivers, and Estuaries.—The following resolution was forwarded to the Secretary of the Conference by the Secretary of this Section:—

"That Mr. John Murray, Prof. Chrystal, Dr. A. Buchan, Rev. C. J. Steward, Hon. R. Abercromby, Mr. J. Y. Buchanan, Mr. David Cunningham, Mr. Isaac Roberts, Dr. H. R. Mill, and Prof. Fitzgerald be appointed a Committee to arrange for an investigation of the seasonal variations of temperature in lakes, rivers, and estuaries in various parts of the United Kingdom in co-operation with the local Societies represented at the Association; and that Mr. John Murray be Secretary."

Dr. H. R. Mill, as representing this Committee, stated that the question proposed had not been fully worked out, but that the few observations made showed relations of a very interesting kind. As a branch of meteorology, this research was particularly promising, and was one in which the co-operation of local Societies would be valuable. He proposed that the Societies situated in the neighbourhood of rivers and estuaries which were willing to undertake this work should appoint some member to observe the temperature daily or weekly, as the case might be, in accordance with the rules to be drawn up by the Committee. It was first proposed to ascertain how many observers would offer themselves in various parts of the country, then to draw up a scheme of observations and arrange for this being adopted.

Mr. G. J. Symons pointed out the necessity in such observations for having a well-considered scheme drawn up, as well as for having absolutely reliable thermometers, without which no observations would be of value. He also asked whether it was proposed that the cost of the instruments should be met by a grant from the British Association, or whether the Societies taking part in the observations should provide their own thermometers.

Mr. De Rance remarked that in the case of the Committee which had been formed for the observation of underground temperatures, and of which Prof. Lebour was a member, the thermometers had been supplied by the Association.

Mr. J. W. Davis raised the question as to whether it would be of use to extend the observations to the streams in manufacturing districts. He also asked what the Committee proposed to consider as an estuary.

The Rev. H. Winwood remarked that it would be necessary in all cases to record the depth at which the thermometer reading was taken. As a point of interest bearing upon the proposed observations, he stated that it had been observed that the temperature of the lakes in the Hebrides had been unusually high this year.

Prof. Lebour stated that the thermometers used by the Underground Temperature Committee had been supplied by the Association, but these instruments were very costly, and only a few observers had taken part in the work. He was of opinion that, if numerous Societies took part in the observations, these should in each case bear the expense.

Dr. Garson expressed a hope that the temperatures would be recorded on the Centigrade scale.

Dr. Mill, in reply, said that he understood that the fact of the investigation being sanctioned by a Committee of Section A was a sufficient guarantee that it should be carried out in a thoroughly scientific manner with properly verified instruments of a uniform pattern, and employed in the same way. The experience of the Scottish Marine Station for three years suggested many precautions which should be adopted in this work. The temperature of streams in manufacturing districts should certainly be ascertained in as many cases as possible, in order to find whether the increase of temperature of a river passing through a manufacturing town is in any sense permanent. The term "estuary" should in his opinion be used as meaning all parts of a tidal river between the upper limit of the tide and the open sea. Each local Society should be asked to supply its own thermometers, but all these should be verified at Kew, or compared by some person appointed by the Committee. The observations would, of course, be made on a uniform plan, and it would, probably, be found more convenient to use the Fahrenheit scale, but the readings could be easily converted, if necessary.

Section C.

Mr. C. E. De Rance, who represented this Section, referred to the work of the three Committees which he had brought under the notice of the Delegates on former occasions, viz.: (1) The Underground Waters Committee; (2) The Erratic Blocks Committee; and (3) The Sea Coasts Erosion Committee. (See last Report.)[1]

The first of these Committees requires information as to the depth of wells, the sections passed through, the height at which the water stands before and after pumping, daily records of the height and chemical analyses of the waters.

The *Erratic Blocks Committee* wants information as to the position, size, and character of boulders of foreign origin that

[1] The constitution of these Committees remains as last year. The Secretaries are:—
Underground Waters, C. E. De Rance, 28 Jermyn Street, London, S.W.
Erratic Blocks, Rev. H. W. Crosskey, 117 Gough Road, Edgbaston, Birmingham.
Sea Coasts Erosion, Wm. Topley, 28 Jermyn Street, London, S.W.
The schedules and all other information will be furnished on application at the above addresses.

may occur in drift-covered areas, and are anxious that the position of the same should be noted on the 1-inch map of the Ordnance Survey.

The *Sea Coasts Erosion Committee*, like the other two Committees, has a circular form of inquiry, which can be obtained on application to Mr. Topley.

With reference to the work of this last Committee, Mr. Topley stated that but little assistance had as yet been received from the local Societies. The Natural History Society of the Isle of Man had undertaken to collect information; and all similar Societies in maritime counties might greatly assist the Committee by local observation as to present changes, and by researches as to past conditions of the coast.

With respect to the work of the Erratic Blocks Committee, Prof. Meldola said that he had been authorized to state, on behalf of the Manchester Geological Society, that several members of that Society had been interesting themselves in the distribution of boulders in their district, and it was expected that their results would be available by the next meeting of the Association. It was also mentioned that Mr. Adamson had been rendering assistance to this Committee on behalf of the Yorkshire Naturalists' Union.

Mr. Ralph Richardson, as the representative of the Edinburgh Geological Society, pointed out that Scotland had been omitted from the localities dealt with by the Erratic Blocks Committee. He stated that much work in this field had already been carried out under the auspices of the Royal Society of Edinburgh, and he hoped the Committee would be able to utilize their results.

Earth Tremors Committee.—Prof. Lebour stated that since the last meeting of the Conference the formation of a Joint Committee by Sections A, C, and G has been agreed to, and the resolution forwarded to the Committee of Recommendations. The resolution was the following:—

"That Sir F. J. Bramwell, Mr. E. A. Cowper, Mr. G. J. Symons, Prof. G. H. Darwin, Prof. Ewing, Mr. Isaac Roberts, Mr. Thomas Gray, Dr. John Evans, Prof. Lebour, Prof. Prestwich, Prof. Hull, Prof. Meldola, and Prof. Judd be a Committee for the purpose of considering the advisability and possibility of establishing in other parts of the country observations upon the prevalence of earth tremors, similar to those now being made in Durham in connection with coal-mine explosions, and that Prof. G. A. Lebour be the Secretary."

Mr. Symons and Mr. Topley made some remarks on the work of this Committee.

Mr. De Rance remarked that the proposed observations might possibly under certain circumstances become connected with the work of the Underground Waters Committee. Thus the Essex earthquake of April 22, 1884, had caused a rise in the level of the water in Messrs. Courtauld's well at Bocking, which had reached its maximum in June of the same year. Since then the level had been gradually falling, and at its present rate it might be expected that the water would be at the same level as it was before the earthquake about next August.

Section D.

Life-Histories of Plants.—Prof. Meldola said that during a recent visit to Oxford he had had an opportunity of hearing a suggestion in the course of a conversation with Prof. Bayley Balfour, which had appeared to him as likely to be of use to the members of local Societies. He had therefore invited Prof. Balfour to attend the Conference and explain his views on the suggested subject, but as that gentleman was prevented from being present he had forwarded the following communication:—

"It appears to me that much good scientific work might be done by members of local Societies in a direction which has not attracted so much attention in Great Britain as it deserves. The discovery and description of new forms, and the distribution of our indigenous plants, are in botany the lines upon which most of the energies of local Societies are principally spent, whilst habit, construction, and generally the features of life-history of plants come in for attention in quite a secondary way. This arises, I think, in great part from the prevalent notion that the facts of the life-history of our common plants are all well known, and that there is little, if anything, more to find out about them. That this is an erroneous idea may easily be shown—witness, for example, the interesting observations recently published by Sir John Lubbock—and there is a field for a great deal of sound work upon plants growing at our doors.

"Within recent years Mr. Darwin's work, followed up by that of such men as Hermann Müller, Kerner, Ogle, and others, has given a stimulus to observations of adaptations between the vegetable and animal kingdoms in connection with pollination in flowers; and many interesting facts about British plants have been brought to light by workers in local Societies. But little has been done for the subject of the vegetative organs of these plants—I mean the arrangement, true nature, and structure of the members that carry on plant-life. In Germany, many years ago, Wydler and Irmisch published a splendid series of contributions to the knowledge of these features in indigenous German plants—why has this not been done for Britain?

"Now, I venture to think that good results would follow if you would bring before the Delegates at the meeting to-day the importance of encouraging the members of their Societies to study the life-histories of indigenous plants in their entirety, *i.e.* from the stage of embryo in the seed up to the production of fruit and seed again. Anyone who will take up this line of study will assuredly derive great pleasure from it, and will be able to add a great deal to the sum of our knowledge of plant-life. Such work can be well combined with the more usual systematic work; it can be easily accomplished, and it will be found to give much additional interest to the study of British botany."

Mr. C. P. Hobkirk considered that Prof. Balfour's letter was a very important one, and that, as therein suggested, the time and energies of the members of local Societies would be far more usefully employed by following the lines indicated by Prof. Balfour than, as at present, in simply collecting, naming, and registering local plants. As far as he was concerned, he was prepared personally, and also on behalf of the Yorkshire Naturalists' Union, which he represented, to do everything in his power to assist in carrying out practically Prof. Balfour's most useful proposition. Although the compilation of local floras was most useful and necessary work, yet the actual life-history of individual forms was now of really paramount importance, and members of local Societies should be urgently requested to carry on this work without delay.

Section H.

Ancient Monuments Act.—The Secretary read the following communication from General Pitt-Rivers:—

"I am much afraid I shall not be able to be present at the meeting of Delegates of local Societies on Tuesday; but the subject is so important for the preservation of these monuments that in case I am not there I write in order that you may know what my view of the matter is.

"Perhaps I cannot do better than state in a few words what the work of the Inspector of Ancient Monuments is, and you will then see what kind of progress is likely to be made without some assistance such as has been proposed,[1] and in what way the assistance of local Societies can be given.

"You are probably aware that in the original Act of 1882 fifty ancient monuments in Great Britain were scheduled as monuments to which the Act could apply at once if the owners were willing. Some persons suppose that by scheduling these monuments they were actually placed under the Act, but this is not the case. The scheduling was done without the knowledge or consent of the owners, and their consent had to be obtained both for these and for every other monument that has been since added to the list. This has entailed the examination and survey of all these monuments which are distributed over England, Scotland, and Wales. The addresses of the owners had to be obtained, and this could only be done on the spot. After that the owners had to be visited personally, for I soon found an official letter, without a verbal explanation, almost invariably produced a refusal. On this account I have of late found it advisable never to approach an owner without a personal introduction, or without doing it in such a way as to induce him to consider the matter favourably. This mode of procedure for the whole country has, of course, taken a long time, and the result has been that about half of these fifty monuments have been voluntarily put under the Act by their owners, and of the remainder some of the proprietors have refused, whilst in the case of others it has been found impracticable owing to peculiarities in the ownership. All the monuments have, however, been carefully surveyed, planned, and drawn, and in every case in which there has been a refusal the owners have stated their intention of taking good care of the

[1] This refers to the work of the Prehistoric Remains Committee of the British Association.

monuments themselves. In one case only a camp has been partly damaged, and this owing to mining operations involving a question of a large sum of money which made it impossible for the Government to interfere. Other non-scheduled monuments have since been added to the list, and the number is steadily but not rapidly increasing.

"The Government makes no allowance for an assistant; not even so much as a man to hold the end of the tape in measuring, without which no proper survey of the monuments can be made, and I have to employ a private assistant, whom I take about with me at my own cost. With his assistance, and by dividing the work with him—I making the necessary notes and measurements while he is drawing—each monument takes on an average about one day; without an assistant the time would be about doubled. After this the owner has to be visited, and as he generally lives at a distance from the monument, this frequently takes another day or more. A great deal of this time might be saved by the assistance of persons living in the localities and with better chance of success.

"I issued a circular to a number of local Societies inviting them to co-operate, but few responded. One instance, however, shows what may be done in this way. Sir Herbert Maxwell has not only sent me the addresses of several owners in Wigtonshire and Kirkcudbrightshire, but, by using his influence with these, has been the means of placing several monuments under the Act. I would suggest that the same course might well be followed by others.

"The recommendation I would make is this:—Local Societies should (1) report to me what monuments in their district they think worthy of being put under the Act; (2) they should send me the names and addresses of the owners; (3) they should communicate with the owners, and, if possible, obtain their consent to have the monuments placed under the Act, subject, of course, to their subsequent acceptance by the Office of Works; and (4) they should report to me any damage that they find being done or contemplated either to the monuments under the Act, or to others not so protected. With such assistance I think that much more rapid progress may be made."

Prehistoric Remains Committee.—Mr. J. W. Davis stated that this Committee had been recommended for reappointment by the Committee of Section H. The recommendation is as follows:—

"That Sir John Lubbock, Dr. John Evans, Prof. Boyd Dawkins, Dr. R. Munro, Mr. Pengelly, Dr. Hicks, Mr. J. W. Davis, Prof. Meldola, and Dr. Muirhead be reappointed a Committee for the purpose of ascertaining and recording the localities in the British Islands in which evidences of the existence of prehistoric inhabitants of the country are found; and that Mr. J. W. Davis be the Secretary."

Prof. Lebour suggested that it would be convenient if, in registering prehistoric remains, the Committee would adopt a uniform scheme of signs—if possible, an international one.

Mr. William Gray stated that the work of registering ancient remains had been carried on for twenty-five or thirty years by members of their Society (Belfast Naturalists' Field Club) and others in Ireland, and they had long felt the want of some central organization such as that of the present Committee. He also alluded to the necessity for a uniform system of signs.

Mr. William White remarked upon the difficulty which private individuals often experienced in approaching the proprietors of ancient remains, and pointed out that individual efforts would be likely to be more successful if members of local Societies could make overtures backed up by the sanction of a British Association Committee such as the present one.

Work of the Corresponding Societies Committee.—The Secretary stated that during the present meeting of the Association an important resolution had been framed at the instigation of Sir Douglas Galton, with the object of extending the powers of their Committee. According to the present rules the Committee was nominated by the Council and appointed by the General Committee, but they had no power of submitting resolutions or recommendations to the Committee of Recommendations or to the General Committee. The present resolution, which was calculated to give them the necessary power, and thus to put them on the same footing as the Committees of the Sections, was as follows:—

"That the Conference of Delegates of Corresponding Societies be empowered to send recommendations to the Committee of Recommendations for their consideration, and for report to the General Committee."

The Secretary had succeeded that morning in getting this resolution passed by the Committees of Sections B and C, and it had been forwarded by them in due form to the Committee of Recommendations, by whom it had also been accepted. It was subsequently submitted to the General Committee, and accepted by them on the understanding that the recommendations so forwarded should not clash with the recommendations sent up by the Sectional Committees.

The Secretary remarked that he would take the present opportunity of explaining away a misunderstanding that had arisen on the part of some of the local Societies. Some of these had nominated Delegates to attend the Manchester meeting without having previously submitted any claim for election as Corresponding Societies. Such Delegates could not be officially recognized by the Association, as it was only those Societies which had been admitted as Corresponding Societies, and which were still on the list, that were thus entitled to be officially represented. According to the Rules no Society can be admitted without first sending in a formal application, accompanied by a specimen of its publications; this application would be considered by the Corresponding Societies Committee, and only in the event of the Society being recommended for election by this Committee, and this recommendation confirmed by the General Committee, would it be admitted to the privileges of a Corresponding Society.

At the termination of the meeting a vote of thanks was passed to Prof. Meldola, on the motion of Prof. Lebour, for the services which he had rendered as Secretary to the Committee and to the Conferences.

THE METEOROLOGY OF OXFORD.[1]

THE forty-second volume of the Observations of the Radcliffe Observatory has recently been published, and is in nearly all respects a continuation of the previous publications. The Radcliffe takes precedence of all our British Observatories as regards the length of time over which the published hourly observations of atmospheric pressure and temperature extend; to which is to be added a commendable fullness, far from common, with which many other observations have been made and given to the public for a long term of years.

At Oxford, atmospheric pressure attains the maximum, 29·760 inches, in June, and falls to the minimum, 29·677 inches, in March, to which the mean of October, 29·680 inches, closely approximates. The annual mean is 29·720 inches; the highest during the previous thirty years being 29·785 inches in 1858, and the lowest 29·572 inches in 1872, the year to be long remembered for its excessive rainfall. Temperature rises to the maximum, 61°·7, in July, and falls to the minimum, 38°·8, in January, the annual mean being 49°·2. The warmest year was 1868, with a mean of 51°·4, and the coldest mean 45°·5 in 1879. Of individual months, the warmest was July 1859, the mean of which was 66°·5, while the mean for February 1855 was only 29°·5, giving thus a mean monthly range of 37°·0. The rainfall reaches the maximum, 2·81 inches, in October, and falls to the minimum, 1·62 inch, in March, and the mean annual amount is 26·42 inches. The extreme annual amounts were 40·42 inches in 1852 and 17·56 inches in 1870. The month of heaviest rainfall was October 1875, when 7·53 inches fell, and the lightest fall was 0·18 inch in September 1865, when temperature was unusually high for the season.

The diurnal curves of pressure approach closer than those of any other British Observatory of which we have records to the seasonal phases of these curves for continental situations. On the mean of the year, the first minimum occurs about 4 a.m., and the maximum at 9 a.m.; and the second minimum at 3.30 p.m. and maximum at 10 p.m.,—the former being earlier in summer and later in winter, whereas the afternoon phases are the reverse of this. In June the time between the first and second maximum is 14½ hours, but in winter only 12 hours.

Of quite exceptional interest are some of the other diurnal phenomena at Oxford, notably the diurnal distribution of thunderstorms, sheet lightning, and auroras. We have compiled the following table showing the sums of the times of occurrence

[1] "Results of Meteorological Observations made at the Radcliffe Observatory, Oxford, in the Year 1884, under the Superintendence of E. J. Stone, F.R.S." (Oxford, 1887.)

of these phenomena during the several hours of the day for the twenty years ending 1884:—

Hours.	Thunder-storms.	Sheet lightning.	Auroras.	Hours.	Thunder-storms.	Sheet lightning.	Auroras.
	Summer—June, July, August.		Year.		Summer—June, July, August.		Year.
Midt. to 1 a.m.	9	14	10	Noon to 1 p.m.	26	0	0
1 to 2 a.m.	5	4	2	1 to 2 p.m.	24	0	0
2 to 3 a.m.	5	1	2	2 to 3 p.m.	21	2	0
3 to 4 a.m.	6	1	1	3 to 4 p.m.	29	2	0
4 to 5 a.m.	4	0	0	4 to 5 p.m.	17	2	0
5 to 6 a.m.	6	0	1	5 to 6 p.m.	22	4	5
6 to 7 a.m.	4	0	1	6 to 7 p.m.	22	3	10
7 to 8 a.m.	7	1	0	7 to 8 p.m.	5	12	26
8 to 9 a.m.	5	0	0	8 to 9 p.m.	3	22	31
9 to 10 a.m.	8	0	0	9 to 10 p.m.	5	41	27
10 to 11 a.m.	7	1	0	10 to 11 p.m.	5	40	25
11 to noon.	21	1	0	11 to midnight	5	26	16

Thus the daily maximum for thunderstorms is from about noon to 7 p.m., being the period of the day covered by the afternoon minimum of atmospheric pressure in summer; but the maximum for sheet lightning is from 8 p.m. to midnight, being the period embraced by the afternoon maximum of pressure. The absolute daily maximum for sheet lightning, it will be observed, does not occur till from 9 to 11 p.m., or till some time after dusk, and cannot therefore be accounted for by increased visibility as darkness sets in. The opinion is widespread that sheet lightning is merely the reflection of a distant flash of lightning. The Oxford observations show, however, that only a small percentage of all the cases admit of being explained in this way. In connexion with the well-defined maximum from 9 to 11 p.m. it may be remarked that there is no region of the globe nearer Oxford than America where thunderstorms with the accompanying true lightning have the daily maximum at the same physical time, 9 to 11 p.m. G.M.T., when sheet lightning has its daily maximum at Oxford.

The curve for auroras has its diurnal maximum substantially at the same time as sheet lightning, or during the time of the evening maximum of pressure. The agreement of these two maxima with this portion of the daily curve of pressure is all the closer when it is considered that the evening maximum of pressure is from one to two hours later in summer when the sheet lightning was observed than in the autumn and spring months when the great majority of auroras occur. These results are of the greatest importance with respect to recent theories regarding thunderstorms, and to suggested connexions between the aurora in arctic and sub-arctic regions and the lightnings of low latitudes. The time of occurrence of the maxima of aurora and sheet lightning from 9 to 11 p.m. indicates, perhaps, a more direct connexion between these phenomena and the evening maximum of pressure than has been suspected. This maximum is mainly due to an overflow of upper aërial currents back to eastward from the longitudes to westward, where at the time the afternoon pressure is at the minimum ("Encyc. Britt.," *Meteorology*, p. 122); and hence at these hours there is more aqueous vapour spread through the higher regions of the atmosphere in its gaseous and fluid states, and also in the solid state of minute spicules of ice, even though no cloud in the finest pencilled forms of the cirrus be visible.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Drs. Routh and Glaisher, Prof. J. J. Thomson, and Mr. A. R. Forsyth have been appointed Examiners in Part II. of the Mathematical Tripos of 1888.

The following appointments of Natural Science Examiners have been made:—Physics: Profs. J. J. Thomson and W. G. Adams. Chemistry: Prof. H. E. Armstrong and Mr. H. J. H. Fenton. Mineralogy: Messrs. T. W. Danby and H. A. Myers (British Museum). Botany: Prof. I. B. Balfour and Dr. S. H. Vines. Physiology: Dr. W. H. Gaskell and Prof. G. F. Yeo. Zoology: Messrs. H. Gadow and W. F. R. Weldon. Geology: Prof. C. Lapworth and Mr. A. Harker. Human Anatomy: Prof. J. Cleland and Dr. A. Hill. Pharmaceutical Chemistry: Mr. Pattison Muir.

At a meeting of the Senate in the Arts School recently, general approval was expressed of the scheme for providing a new room for botanical microscopy. The scheme for new anatomical and physiological rooms was not so entirely approved, some persons wishing to retain the ugly old Anatomical Museum and buildings, and also considering that the requirements of the Medical School had not been sufficiently considered.

Mr. W. Bateson, M.A., Fellow of St. John's College, has been elected to the Balfour Studentship.

Group E (Natural Science), in the Higher Local Examination, attracts a diminishing number of candidates, we are sorry to see. Only 36 presented themselves this year as against 73 in 1879; but 10 candidates gained a first class this year, as against 4 in 1879: 35 failed then, only 5 this year. Elementary Biology is reported on fairly this year; but Elementary Chemistry does not seem to have been studied practically, and problems were not satisfactorily dealt with. Only four candidates passed in Physics. The Physiology, Zoology, and Geology papers were well answered; but in Botany the general standard was decidedly low.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, November 2.—Dr. D. Sharp, President, in the chair.—Mr. Stevens exhibited a specimen of *Acidalia immorata*, L., purchased by him some years ago at the sale of the collection of the late Mr. Desvignes. He remarked that specimens of the insect lately captured near Lewes had been described last month by Mr. J. H. A. Jenner as a species new to Britain.—Mr. Adkin exhibited, and made remarks on, a series of male and female specimens of *Arctia mendica* from co. Cork; also, for comparison, two specimens of *A. mendica* from Antrim, and a series of bred specimens from the London district.—Mr. Enoch exhibited a specimen of *Calocoris bipunctatus* containing an internal parasitic larva.—Dr. Sharp exhibited three species of Coleoptera new to the British list, viz. *Octhebius auriculatus*, Rey, found some years ago in the Isle of Sheppey, but described only quite recently by M. Rey from specimens found at Calais and Dieppe; *Limnius rivularis*, Rosenh., found by Dr. J. A. Power at Woking; and *Tropiphorus obtusus*, taken by himself on the banks of the Water of Cairn, Dumfriesshire.—Dr. Sharp also exhibited a *Goliathus* recently described by Dr. O. Nickerl as a new species under the name of *Goliathus atlas*, and remarked that the species existed in several collections, and had been supposed to be possibly a hybrid between *G. regius* and *G. cacicus*.—Mr. Eland Shaw exhibited two species of Orthoptera, which had been unusually abundant this year, viz. *Nemobius sylvestris*, and *Tettix subulatus*.—Mr. E. B. Poulton exhibited the cocoons of three species of Lepidoptera, in which the colour of the silk had been controlled by the use of appropriate colours in the larval environment at the time of spinning up. He said this colour-susceptibility had been previously proved by him in 1886 in the case of *Saturnia carpini*, and the experiments on the subject had been described in the Proc. Royal Society, 1887. It appeared from these experiments that the cocoons were dark brown when the larvæ had been placed in a black bag; white when they had been freely exposed to light with white surfaces in the immediate neighbourhood. Mr. Poulton stated that other species subjected to experiment during the past season afforded confirmatory results. Thus the larvæ of *Eriogaster lanestris* had been exposed to white surroundings by the Rev. W. J. H. Newman, and cream-coloured cocoons were produced in all cases; whilst two or three hundred larvæ from the same company spun the ordinary dark brown cocoons among the leaves of the food-plant. In the latter case the green surroundings appeared to act as a stimulus to the production of a colour which corresponded with that which the leaves would subsequently assume. Mr. Stainton suggested that larvæ should be placed in green boxes, with the view of ascertaining whether the cocoons would be green. It had been suggested that the cocoons formed amongst leaves became brown because the larvæ knew what colour the leaves would ultimately become. The discussion was continued by Mr. Waterhouse, Dr. Sharp, Mr. McLachlan, and others.—Mr. S. Klein read "Notes on *Ephestia kuhniella*," and exhibited a number of living larvæ of the species, which he said

had been recently doing great damage to flour in a warehouse in the East of London.—Mr. A. G. Butler contributed a paper "On the species of the Lepidopterous genus *Euchromia*; with descriptions of new species in the collection of the British Museum."—Lord Walsingham communicated a note substituting the generic name *Homonymus* for the generic name *Ankistrophorus*—which was preoccupied—used in his "Revision of the genera *Acrolophus* and *Anaphora*," recently published by the Society.

PARIS.

Academy of Sciences, November 14.—M. Janssen in the chair.—Note on certain definitions in mechanics, and on the unities in current use, by M. de Freycinet. In supplement to the remarks already made in his treatise on mechanics, the author here deals more fully with the notions involved in such terms as *force, weight, mass, bulk*, and shows that considerable advantage might be gained by slightly modifying the generally accepted unities. Fresh definitions are suggested of the unities of length, volume, weight, force, velocity, &c.—On the state of the potassa present in plants and the soil, and on its quantitative analysis, by MM. Berthelot and André. In continuation of a previous communication on this subject, the authors here study the condition and process of analysis of the potassa in living plants, and in the humus produced by their disintegration.—On waterspouts, by M. D. Colladon. In reply to M. Faye's strictures, the author illustrates his views by means of an instantaneous photograph, showing that under certain conditions two waterspouts may be generated, one ascending, the other descending, and crossing each other.—On MM. Houzeau and Lancaster's "Bibliographie Générale de l'Astronomie," by M. Faye. A well-merited eulogium is passed on the authors of this great work, who have earned the lasting gratitude of astronomers for accomplishing their vast undertaking in such a thoroughly satisfactory manner. The Bibliography constitutes a systematized catalogue of all astronomical publications that have appeared from the remotest times down to the present day. Although not absolutely exhaustive, the omissions do not appear on examination to be very numerous; but unfortunately only 300 copies have been issued of a work which should find a place in every Observatory and in every scientific library in the world. M. Houzeau has enriched the first volume with a valuable philosophic history of astronomy, which will be found extremely interesting, especially to those students who have been unable to follow the recent discoveries of specialists on the state of astronomical science amongst the Egyptians, Assyrians, and other ancient peoples.—New nebulæ discovered at the Observatory of Paris, by M. G. Bigourdan. These discoveries have been made during the years 1884–87 with the equatorial of the West Tower. Most of the nebulæ are very weak, and some, indicated as more or less stellar, might, strictly speaking, be regarded as simple stars, it being often quite impossible to distinguish between a small nebula and a star of small magnitude. The positions are approximately given for the mean equinox of 1860·0, in order to facilitate comparison with J. Herschel's "General Catalogue of Nebulæ and Clusters of Stars," and its supplement by Dreyer.—On the theory of magnetism, by M. P. Duhem. From a comparative study of magnetic and diamagnetic bodies the theorem is deduced that all magnetic bodies are attracted from great distances by permanent magnets, but that nothing can be affirmed regarding diamagnetic bodies. A theorem is also established which sets forth the difference between magnetic and diamagnetic bodies, and some remarks are appended regarding the magnetizing of crystals.—Measurement of the heights and movements of clouds in Spitzbergen and Upsala, by M. Nils Ekholm. These comparative studies are based on fifty meteorological observations taken during the Swedish expedition of 1882–83 to Spitzbergen, conducted by the author.—On a new method of formation of safranines, by MM. Ph. Barbier and Léo Vignon. Having in a previous communication explained a special method of forming substituted safranines, the authors here describe a new process for producing phenosafranine and its homologues.—On a new artificial serum intended to dilute the blood for the purpose of counting its globules, by M. Mayet. For the serum here described it is claimed that it is free from the disadvantages of others in general use. It consists of distilled water, 100 gr.; neutral phosphate of anhydrous and pure sodium, 2 gr.; with cane sugar to raise the density of the liquid to 1·085.—On antipyrine as a remedy against sea-sickness, by M. Eugène Dupuy. The author declares that for some time back he has successfully employed this substance as a prophylactic against sea-sickness. He recommends a dose of 3 gr. to be taken daily for three days before sailing, to be continued if necessary during the voyage. Without claiming to have discovered an absolute specific, he considers that the success hitherto attending the use of antipyrine justifies the hope that in this substance we possess a more or less efficacious remedy against one of the chief terrors of travelling by sea.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

A Dictionary of Place-Names: C. Blackie, 3rd edition (Murray).—Report of the Commissioner of Agriculture, 1885 (Washington).—The Cremation of the Dead: Dr. H. Erichsen (Haynes, Detroit).—Down the Great River: Capt. W. Glazier (Hubbard, Philadelphia).—The Creator, and what we may know of the Method of Creation: Dr. W. H. THE MATHEMATICAL THEORY OF PERFECTLY ELASTIC SOLIDS.

An Elementary Treatise on the Mathematical Theory of Perfectly Elastic Solids; with a Short Account of Viscous Fluids. By William John Ibbetson, M.A. (London: Macmillan and Co., 1887.)

IT is strange that students should have had to wait till the present time for a systematic English text-book on the mathematical theory of elastic bodies. The want has been decidedly felt at Cambridge since the introduction of the subject into the schedule for the Mathematical Tripos in 1873; and though parts of Thomson and Tait's treatise on natural philosophy, and the reprint of Green's papers, had already brought a large amount of useful matter into an accessible form for those who had not time or opportunity to read the original memoirs, still it was found that learners, naturally looking for some compendious account of the whole subject, generally fell back upon M. Lamé's treatise.

The book at present under notice will supply this want satisfactorily. The plan on which it has been written is excellent in idea, and has on the whole been followed out well, though perhaps there is here and there some want of proportion, as for instance in the elaborate and purely mathematical details of Chapter V.

It is, no doubt, a difficult matter to decide what results of mathematical analysis should be introduced without proof in a treatise on mathematical physics, and there is little question that, as a matter of convenience to the reader, it is wiser to err on the side of assuming too little knowledge rather than too much. On the other hand, wherever questions of pure mathematics are introduced and discussed at length, they should be such as have a direct bearing on important parts of the physical subject. Now the general forms of the dynamical equations for an elastic body in terms of curvilinear co-ordinates, which are established in Chapter V. after a considerable amount of preliminary analysis, are so complicated as to be practically valueless. Indeed, the one case referred to is dismissed in a single paragraph. The special forms for polar and semi-polar co-ordinates, often to be used with advantage, may be very much more simply established independently.

To return to the general plan of the book. It commences with a short preliminary chapter, headed "Properties of Elastic Solids," in which, after showing that the subject cannot be profitably considered from the point of view of molecular structure, the author defines the ideal solid which must for purposes of analysis replace the real body.

In Chapter II. the general properties of strain are treated very clearly and at considerable length. A little more consideration might perhaps have been given with advantage to finite homogeneous strain. No fewer than three quadrics are introduced for the purpose of putting results into a geometrical form, viz. the strain ellipsoid, the elongation quadric, and the position ellipsoid; while in the succeeding chapter, on "The Analysis of Stress," four surfaces—the first, second, third, and fourth stress quadrics—are used for a similar purpose. It can hardly be doubted that so great a number of surfaces will tend rather to confusion than to that clearness of conception of the properties of strain and stress for which they are presumably introduced.

The nature and mode of specification of stress is carefully expounded in Chapter III., and the dynamical equations to be satisfied throughout the body and over the boundary are obtained in terms of the stress-components. Attention should be called to a statement in § 153 of this chapter, as likely to mislead the student. It is to the effect that "the component stresses are to be considered as small quantities of the first order." Though in a certain sense this is true, it is not true that the ratio of the stress per unit area to, say, the weight per unit volume of the body is a small proper fraction, and this surely is the strict sense the words should bear.

The next chapter, on "The Potential Energy of Strain," is excellent. The method is similar to that used by Thomson and Tait; and the successive simplifications introduced into the expression for the potential energy of the strained body by considering successively greater degrees of symmetry of structure, leading up to perfect isotropy, are well shown. It is also pointed out that from the definition of an isotropic body, its potential energy is necessarily a function of the invariants of the strain, thus reducing the number of independent elastic constants in this case at once to two. Having thus arrived at a definite conception of the isotropic elastic solid, the author expressly limits all the investigations that follow to the case of such a body. From the expression obtained for the potential energy, forms are deduced for the stress components in terms of the strain components and the elastic constants, and thence finally the dynamical equations are obtained in terms of the displacements.

In Chapter V., as already stated, these equations are thrown into new forms, and the remainder of the book is devoted to their solution under various conditions as to the nature of the applied forces and tractions and the form of the body.

As an introduction to the consideration of particular questions the following five general theorems are proved, viz.:—

"(i.) that a state of strain cannot be maintained unchanged without the action of applied forces or surface tractions:

"(ii.) that the state of strain maintained by a given system of equilibrating applied forces and surface tractions is therefore perfectly determinate:

"(iii.) that the most general free motion of an elastic solid consists of a number of superposed harmonic oscillations of the particles about their natural positions:

"(iv.) that the most general motion of such a body under the action of an equilibrating system consists of a number of superposed harmonic oscillations of the particles about the equilibrium positions that would be maintained by the system:

"(v.) that a system of applied forces varying as a simple harmonic function of the time gives rise to forced harmonic oscillations of the particles of the same period about their natural positions."

The proofs given of these theorems, and especially of the third, are rather unnecessarily long; but, with a view to avoiding repetition later on, it is certainly convenient

to have them established as a foundation from which to start.

The problem of free vibrations is first treated, and as an example the propagation of plane waves of (i.) normal, (ii.) tangential, displacement is investigated. It is a pity that the author has not here taken the opportunity of illustrating some previous remarks on the discontinuity of the forms of the strain and stress components which necessarily accompanies a change in the nature of the medium, by considering the question of the reflection and refraction of plane waves.

The general form of the solution of the equations for forced vibrations is next investigated. Then follows the general question of equilibrium. As a simple example the case of a cylindrical tube under external and internal normal pressures is first treated. It is almost annoying to find the solution of this time-honoured question obtained by starting from the general equations, and whittling them down till the very simple conditions are fulfilled. The equilibrium of a solid sphere, with either surface tractions or displacements given, is treated exactly as in Thomson and Tait's work. The chapter of general solutions closes with an account of Airy's general method for plain stress, with a couple of examples. The printing was unfortunately so far advanced that this had to be left; though before the book appeared the author had himself shown, in a communication to the London Mathematical Society, that these examples of Airy's are faulty, and that the method applies only to a very limited class of cases.

Chapter VII. consists mainly of a capital exposition of the solution of St. Venant's problems of the torsion and flexure of prisms. These problems are probably, from a practical point of view, the most important for which an exact solution has been obtained. The author brings out well the bearings of the nature of the solutions on practical questions of construction. The elastic equilibrium and small motions of wires, whether straight or curved, are deduced directly from the results of St. Venant's problems. In connection with this part of the subject, certain interesting questions of stability, due to Mr. Greenhill, are discussed.

Some cases of the equilibrium and vibrations of plates and shells are considered in Chapter VIII. For the equilibrium of a plate of uniform thickness under a system of surface tractions parallel to its faces and acting on its edges, a solution is obtained by analysis very similar to that used in St. Venant's problem. The case of a thin plate under the action of applied faces satisfying certain conditions is quoted from Thomson and Tait again.

Two short chapters headed "Impact" and "Viscosity" complete the volume. The former consists of the solution of two problems, one of which, as the author implies, has nothing to do with impulsive change of motion. Indeed, as is well known, the exact treatment of the impact of elastic bodies involves difficulties, even in comparatively simple cases, which have not yet been overcome. In the last chapter the alteration in the form of the dynamical equations is determined, which results from supposing the shearing stress to vary partly as the shear and partly as its rate of change.

Having thus given some account of the plan of the book and the way in which it has been carried out generally, we may offer some remarks on matters of detail. It may be said at once that as regards accuracy there is a good deal to be desired. The table of errata might have been tripled, and would not then have contained all the misprints. In §§ 299, 306, the wholesale omission of signs of summation in the equations makes the analysis, as given, incorrect; and there is little doubt but that anyone to whom the matter treated was new would be completely baffled. The inaccuracies, moreover, are not confined to mere misprints. There are one or two positive mistakes in the mathematics. Thus at the bottom of p. 58 it is implied that some condition is necessary in order that a family of surfaces, $f(x, y, z) = \xi$ (an arbitrary parameter), may have a system of continuous curves cutting them at right angles; and in a note at the foot of p. 298 it is stated that, supposing this (entirely imaginary) condition satisfied, two other systems of surfaces can always be found cutting each other and the former surfaces everywhere at right angles. Now the three parameters of such a triple system of surfaces have to satisfy three independent partial differential equations, and hence no one of the three can be taken arbitrarily. Statements and reasoning are, in several passages, founded on this erroneous conception. Closely allied with this is the construction given in § 216 for tubes of stress. It is here practically assumed that a given continuous system of curves can always be cut at right angles by a family of continuous surfaces.

An appendix at the end of Chapter II., on "The Geometry of Strains," might have been omitted with advantage. It has no very obvious connection with the preceding chapter, but is devoted to an apparently new classification of vector quantities, in which a velocity and a force are the types of the one group, while an angular and a couple are those of the other! Again, in §§ 270, 271, the solution of a physical problem is made to appear to depend on the choice of an origin. The question treated is the free normal vibrations of a plate; and, after using d and $-d'$ to denote the abscissæ of the two faces, and making the result appear to depend on d/d', the question is *simplified* by taking the origin midway between the faces. Indeed, frequently throughout the book one is reminded of Clerk Maxwell's remark on "the state of a mind conscious of knowing the absolute position of a point."

These slips, such as they are, and an occasional obscurity of language, are but slight blemishes on a valuable book. A friendly but independent criticism of the proof-sheets while the book was passing through the press might have removed them all, and no doubt will in a new edition.

The figures throughout are excellent.

THE VOLCANIC AND CORAL ISLANDS OF THE SOLOMON GROUP.

The Solomon Islands: their Geology, General Features, and Suitability for Colonization. By H. B. Guppy, M.B., F.G.S., late Surgeon R.N. (London: Swan Sonnenschein, Lowrey, and Co., 1887.)

SURGEONS in Her Majesty's navy are favoured beyond most men in the possession of abundant leisure and freedom from many of the common cares of

life. But in spite of the frequent changes of scene which they enjoy, or endure, and their unique opportunities for pursuing scientific researches, and in spite of their early acquaintance with elementary treatises on several branches of science, it is only at rare intervals that naval surgeons appear as observers or investigators. The unusual occasionally happens, and in the work by Mr. Guppy on the Solomon Islands we have an admirable example of what may be accomplished by an energetic observer alive to his advantages.

In this volume it would not be difficult to point out many imperfect forms of expression, some avoidable confusion in arrangement, even a few conclusions that the facts hardly appear to warrant; but these sink into insignificance when compared with the mass of valuable material from which they might be culled.

The object of the book is to describe fully, but in a general way, the author's geological observations on the islands of the Solomon Group, little space being devoted to the other subjects mentioned in the title. It is a compendium of important facts, most of them new to the scientific public. Perhaps the Journal of the Geological Society is hardly suited for recording a series of laborious and detailed observations on the rocks of a remote archipelago, and the publications of the Royal Society of Edinburgh—where detailed papers by Mr. Guppy appear—may not be read by all geologists. It may not be inappropriate, in these circumstances, to mention a few of the facts observed by Mr. Guppy and recorded in this volume.

The book is divided equally between the description of volcanic and calcareous islands, and is illustrated by maps and sections.

The volcanic rocks collected on the islands were submitted for mineralogical analysis to Prof. Judd and Mr. T. Davies; the calcareous formations were studied by Mr. John Murray; and the remains of animal life, both foraminiferal and coral, are being examined by the leading specialists; hence the work is enriched by the labours of well-known men, and the "gold" of the author's data impressed with the "guinea-stamp" of recognized authority.

The volcanic islands of the group are divided into two classes. First, those of comparatively modern formation, composed mainly of little-altered augite-andesites, andesitic pitchstones, tuffs, and agglomerates: these islands still preserve the volcanic outline and sometimes give evidence of recent activity by terminating in craters with hot springs or fumaroles. The second class is composed only in part of these rocks, and in part of much more ancient crystalline masses consisting chiefly of altered dolerites, quartz-diorites and -porphyries, and serpentines. Some islands of the latter class exhibit an extraordinary diversity in petrological character. Fauno, the description of which is illustrated by a geological map, is an interesting instance of this. The northern end of the island is occupied by a precipitous mountain of andesitic tuff sloping steeply down from an altitude of 1900 feet to a narrow isthmus, 150 feet high, composed of hornblende-augite-andesite, and leading to a sickle-shaped peninsula of successive hills connected by low strips of rock. The composition of this crescentic tongue is successively altered dolorites, quartz-porphyries, quartz-andesites, hornblende-andesites, and altered dolerites again. These rocks, almost invariably massive and unassociated with tuffs or agglomerates, each in turn occupy the whole breadth of the peninsula. The mode of formation which Mr. Guppy demonstrates for this promontory is illustrated in various stages by several other islands. A series of small volcanoes arising in a crescentic form, and each pouring out a characteristic lava, were gradually elevated and so brought into connection. Rapid denudation, caused by the great rainfall of the region, wore off the volcanic contours and reduced the chain of peaks to a series of "necks" in close juxtaposition. The comparative rarity of fragmental volcanic rocks, and the mineralogical constitution of the massive crystalline lavas of the surface, indicating their solidification at great depths, prove extensive denudation to have taken place all over those islands.

The main interest of the book centres in the researches of Mr. Guppy on calcareous deposits. He is the only geologist who has visited this most instructive group of coral islands; and he describes what he saw there with a straightforward simplicity that compels confidence in the accuracy of his observations, and affords to those who may find his theory insufficient all possible data for disproving it.

Mr. Guppy gives the following classification of the limestones of a "coral island" in the Solomon Group as revealed to him by the walls of the river gorges he explored:—

Group I.—*Coral Limestones*, properly so called.

Group II.—*Coral Limestones* which have the composition of coral muds or sands now forming near coral reefs. There are three subdivisions of this group: (1) crystalline limestone, in which coral plays a secondary part, and remains of calcareous Algæ and mollusks predominate; (2) chalky limestones; (3) homogeneous fawn-coloured limestones, often crystalline.

Group III.—*Rocks of the composition of volcanic mud and pteropod ooze*, containing also numerous Foraminifera. These are subdivided into (1) partially consolidated volcanic muds; (2) partially consolidated pteropod ooze; (3) hard limestones.

Group IV.—*Foraminiferal Limestones*, or consolidated "Globigerina ooze." There are two classes: (1) composed chiefly of tests of both pelagic and bottom-living Foraminifera; (2) chiefly composed of the tests of pelagic Foraminifera.

Group V.—*Rock resembling a consolidated deep-sea clay* (Red Clay).

The two last-named groups were certainly deposited at depths not much less than 2000 fathoms in an ocean far from continental land, and their existence above sea-level is now for the first time proved.

From all the facts that could be ascertained regarding the coral formations of the group, certain inferences were drawn, which we give in the author's own words:—

"The first is self-evident, viz. *that these upraised reef masses, whether atoll, barrier reef, or fringing reef, were formed in a region of elevation*. . . . It is apparent that Mr. Darwin's theory of coral reefs, which ascribes atoll and barrier reefs to a movement of subsidence, cannot be applied to the islands of the Solomon Group. . . .

"The second inference is, *that such upraised reefs are of moderate thickness, their vertical measurement not exceeding the usual limit of the depth of the reef-coral zone.*

. . I never found one that exhibited a greater thickness of coral limestone than 150 feet, or at the very outside 200 feet. . . .

"The third inference is, *that these upraised reef masses in the majority of islands rest on a partially consolidated deposit which possesses the characters of the 'volcanic muds' that were found, during the 'Challenger' Expedition, to be at present forming around volcanic islands.*

"The fourth inference is, *that this deposit envelops anciently submerged volcanic peaks.*"

Mr. Guppy states that his observations have made him a strong adherent of the theory of formation of coral islands advanced by Mr. Murray.

These observations are indeed crucial between the theories of subsidence and of solution, and point towards the newer. The theory of subsidence demands that a coral reef rising from deep water must be of enormous thickness, and rest upon volcanic or fragmental rock; that of solution requires that the reef be of slight thickness and rest on volcanic rock, or consolidated terrigenous mud, or pelagic ooze. According to the former the reef grows on the whole vertically; according to the latter its main extension is horizontal. Two of Darwin's principal objections to the early conception of coral islands were that it was absurd to suppose that submarine mountains were numerous enough to provide foundations for all the known reefs, and that it was impossible to imagine sedimentation taking place at great distances from land. The recent work of telegraph ships along the West Coast of Africa and elsewhere has shown the extreme probability of submarine mountains existing in large numbers throughout the ocean; the cruise of the *Challenger* proved that the shells of pelagic organisms, wind-borne and meteoric dust and volcanic ashes spread by ocean-currents produce perceptible sedimentation in mid-ocean at a rate varying in some inverse proportion to the depth.

Murray's theory can be brought readily to the test of observation and experiment; Darwin's cannot. It has been shown in the laboratory that calcium carbonate is soluble in sea-water, and is dissolved in greater amount in water containing carbonic acid especially when under pressure; the decomposition of dead corals and the respiration of living ones supply carbonic acid to aid in the removal of their calcareous remains. If atolls are formed in areas of elevation, they may ultimately be seen and measured: if only in regions of subsidence, measurement is impossible, and the vertical extent of the coral limestone can only be guessed at.

It must be confessed that the theory of solution in reef-building has not yet been put before the world with any approach to the completeness, lucidity, and grace with which Darwin convinced and enchained the scientific mind. The theory of subsidence is so beautiful, simple, and satisfactory, that very strong evidence is required to shake it; but in the history of science men have more than once been forced to say of a simple and satisfactory doctrine—

> "'Twas beautiful,
> Yet but a dream, and so—Adieu to it!"

Neither Murray nor Guppy has proved the subsidence theory to be a dream. Still, the solution theory has been plainly set forth, and here we have facts which amount to an absolute proof of its truth for one important group of coral islands. The proof is none the less convincing because it is restricted in its application; for it is concrete and complete in itself, not abstract and cumulative like the evidence for the subsidence theory. Mr. Guppy has demonstrated that the old theory fails and the new succeeds in explaining the formation and structure of the Solomon Islands, and coming at the present time this supplies a powerful argument for the general applicability of the solution theory—an argument that it will not be easy to set aside.

The book is short and interesting; and, besides the important features we have alluded to, it contains much information about the islands visited, and the author's adventures there.

HUGH ROBERT MILL.

AGRICULTURE IN SOME OF ITS RELATIONS WITH CHEMISTRY.

Agriculture in some of its Relations with Chemistry. By F. H. Storer. Two Vols. (London: Sampson Low, Marston, Searle, and Rivington, 1887.)

THIS work, by the Professor of Agricultural Chemistry at the Harvard University, is based on a course of lectures delivered annually by the author. It is addressed to students of agriculture and persons fond of rural affairs, rather than to students of chemistry. Free use has been made of German publications in agricultural chemistry, and of the writings of Prof. S. W. Johnson, of Newhaven, Connecticut. Some of the matters treated of in his two well-known books, "How Crops Grow" and "How Crops Feed," have been omitted, or only lightly touched, in the present volumes, which are therefore, to a certain extent, a supplement to those books.

The present volumes treat of the chemistry of the atmosphere, of waters, of soils, and of manures, and of their several relations to plants; the chemistry of animal life and nutrition is not dealt with. A large amount of valuable information, partly of historical interest, has been brought together; and much of it is presented in the somewhat old-fashioned English of the best writers of New England.

One illustration given by the author, to show that liquids penetrate into plants through their roots, we do not think very happy. He notes an observation made by himself, that Indian corn made to sprout in a flower-pot and watered with milk had white leaves; and he suggests that the minute particles of solid matter in the milk must have entered the plant and caused the whiteness. He admits, however, that the whiteness may have been due to chemical action. In noticing the growth of plants in artificial light, he hardly gives sufficient credit to the observations of Siemens and of Dehérain on growth in the light of the electric arc, both uncovered and variously shaded. Mr. Storer has scarcely that respect for earthworms with which Darwin has imbued us, for on the only occasion he mentions them he styles them pernicious, on the ground that harm is done to plants in pots by their casts, which become slimy mud when watered, and thus clog the pores of the earth and the roots of the plants.

In vol. i. p. 295, a serious mistake occurs, though

doubtless by oversight: it is stated that nitrate of soda used as a top-dressing for mowing-fields that contain true grasses "favours the growth of clover rather than of grass." The reverse of this is the truth. There is a good chapter on irrigation, in which it is pointed out that, "in spite of all that has been done of late years in California and the adjacent regions, it is still probably true that no other subject relating to agriculture so much needs to be attended to by the American people as this matter of watering the land." The questions of the disposal of excreta and of sewage are dealt with in their chemical aspects. Perhaps hardly due credit is given to the latest improvements in some precipitation processes for clarifying sewage, but we are glad to see that the author fully realizes that the sewage subject is essentially a sanitary and not an agricultural question. He also exposes some economic fallacies as to the value of sewage by citing various instances in which valuable matters are found at our doors so diluted as not to be worth the cost of collecting or saving. One illustration is the presence of gold in the clay of Philadelphia—1 of gold in about $1\frac{1}{4}$ million of clay. If the gold from the bricks of the houses could be brought to the surface in the form of gold-leaf, on each brick would be a golden surface of 2 square inches. In the clay beneath the portion of the city already built over is 126 million dollars' worth of gold, yet no one dreams of extracting it. So, except under very favourable conditions for the sewage, valuable manures may be obtained more cheaply than from sewage.

The necessity for the selection of ripe, as well as pure, seeds for sowing, and especially on poor soils, is insisted on and illustrated by records of experiments. The great importance, whether for good or evil, of micro-organisms to the farmer, is often pointed out; and the writer discusses the question of the sources of nitrogen available for plants, and the very important question as to the fixation of free nitrogen from the air by humus or by clay soils. The conclusions of Berthelot, Armsby, Dehérain, and others are stated, and the author regards it as proven, in the light of existing knowledge, that some nitrogen from the air is really fixed as an incident to certain fermentations which occur in the soil. This much debated and debatable point, which is of the utmost economic importance, still requires further elucidation; and we may hope that some further light will be thrown on it by the researches of Sydney Vines on the nutrition of the common bean.

The general nature of the changes brought about in the character of farming by railways and steamships, and the conditions which lead to "high" or to "low" farming, are discussed. An observation of Washington in a letter to Arthur Young is worth recording, in this connexion: "An English farmer must have a very indifferent opinion of our American soil when he hears that an acre of it produces no more than eight to ten bushels of wheat; but he must not forget that in all countries where land is cheap and labour is dear the people prefer cultivating much to cultivating well."

Special chapters are given to barley and oats, and there are three chapters on pastures, grass, and hay, mainly from a New England point of view. In one of these chapters it is stated that the East Anglian word "rowen" for "aftermath," used by old writers, but now, we believe, confined to parts of Suffolk, is in common use in New England.

One minor defect, which might have been remedied by an editor of the English edition, is the use throughout the book of many different systems of weights and measures, *e.g.* the long (English) ton of 2240 pounds, the short (American) ton of 2000 pounds, pounds and bushels per acre as well as kilogrammes per hectare, and German pounds per morgen, per Saxon acre, and per Hessian acre, and even quintals per acre. A reduction of these to one system would have rendered the results more comprehensible, and comparisons easier. Also, a few of the chemical names are not those now in use in this country, and the use of the terms bi-phosphate of lime and di-calcic phosphate as synonymous is very misleading.

For the sake of the British farmer, who is not such a reading man as his American *confrère*, we could wish that some of the subjects had been rather more digested, and that more illustrations had been drawn from English sources, but thanks are due to Mr. Storer for a very suggestive work, that can be confidently recommended to those interested in agriculture for perusal and careful study during the long winter evenings. It cannot fail to awaken a more intelligent interest in the physics and chemistry of the farm. Moreover, notwithstanding the author's modesty, it will be found very useful to the student of agricultural chemistry.

WEATHER.

Weather: a Popular Exposition of the Nature of Weather Changes from Day to Day. By the Hon. Ralph Abercromby. (London: Kegan Paul, Trench, and Co., "International Scientific Series," 1887.)

THE author of this book has undertaken a task the difficulty of which has deterred all previous writers, for FitzRoy's "Weather Book" can hardly be termed a text-book of the subject, and, moreover, it was written at a date at which weather telegraphy was in its infancy. The books which have appeared during the last two decades have been either manuals mainly for the use of seamen, like the Barometer Manuals of the Meteorological Office; or explanations of the interpretation of weather charts, like Mr. Scott's "Weather Charts and Storm Warnings," of which the third edition was lately noticed in these pages. The idea of telling an isolated observer how to employ local weather signs and the manifold modifications of clouds in aiding his own judgment of local weather has not hitherto been adequately carried out.

Mr. Abercromby is peculiarly well qualified for the task of preparing a weather text-book, for not only is he gifted with an unusual faculty of observing weather phenomena, and especially clouds and their changes in this country, as is proved by the papers he has read on various occasions; but he has had more leisure to travel to "foreign parts" than falls to the lot of most meteorologists. The book relates to weather in general, as distinguished from storms, and not merely to the weather of the British Isles; for, though the latter subject occupies most of the work, the information given as to the weather over more extensive areas, such as those of the North Atlantic and the United States, is most instructive and valuable. The

work is divided into two sections, elementary and advanced, of which the former is about one-fourth of the bulk of the latter. The reader must not go away with the idea that the volume contains no original views, for, as Mr. Abercromby says in his preface, "the results of many of the author's original and unpublished researches are included in its pages, such, for instance, as the explanation of many popular prognostics; the elucidation of the general principles of reading the import of cloud-forms; the classification of those cases in which the motion of the barometer fails to foretell correctly the coming weather; and the character of that kind of rainfall which is not indicated in any way by isobaric maps."

Mr. Abercromby's pages convey small consolation to adventurous weather prophets, such as Mr. Wiggins or the framers of the *New York Herald* announcements. At p. 433 we read: "From eight to twelve hours seems to be the furthest time for which forecasts can be issued in advance, and even then many local details cannot be given." Again, at p. 426 he says: "On the whole, we see that the crude notion of forecasting European storms from the United States contains some elements of truth, but that still, from the nature of cyclone motion, the idea can never be used in practical forecasting." His statements as to the impossibility of practically predicting weather by observations of sun-spots are also made with great care.

The most interesting chapters, at least to the ordinary reader, are those which relate to weather prediction, for isolated observers. As regards the formation of clouds and their indications, Mr. Abercromby sets forth the results of much research, but in our opinion he speaks somewhat too decidedly on points which are still *sub judice*.

We welcome the book most cordially, and anticipate a considerable demand for it. We may say, however, that in several places we have noticed slips in the wording, and that the orthography of some of the foreign names is not quite "according to Cocker." In some cases the author's phraseology is not quite clear, and paragraphs have to be read repeatedly before their precise meaning is taken in.

OUR BOOK SHELF.

Class-book of Algebra Examples for Middle and High Schools. Part II., for High Schools. By John Cook, M.A., Principal, Central College, Bangalore. (Madras: printed at the Lawrence Asylum Press, Mount Road. 1887.)

THIS book contains, in addition to the examples which form the main part of the volume, an "Introductory Summary of Rules and Formulæ," extending to about one-third of the whole contents. Although Mr. Cook in his preface lays special stress on this summary, we are by no means sure that its introduction into the volume is an improvement. It is insufficient to allow the student to dispense with the use of a text-book; and a student, who desired to refresh his memory about some particular method or formula, would do better to read it up in his text-book, than to refer to a set of stereotyped rules. Such a summary has the positive disadvantage that it inclines the student to conceive of algebra as consisting entirely of a set of rules, proceeding he knows not whence and leading he knows not whither—a conception which it is one of the chief duties of a teacher of algebra steadily to combat. In parts of this introduction, moreover, there is a looseness of method which is apt to prove very misleading to the student. To refer to only one or two cases in point, we would mention in the first place a confusion between an integral or a rational number and an integral or a rational function. This confusion is shown in the case of division (p. 10) and in the case of root-extraction (pp. 46 and 51). Again, Mr. Cook defines (p. 43) the G.C.M. of two or more fractions, a conception which is perfectly useless in algebra, and only tends to confuse the mind of the learner as to the real meaning of the algebraical G.C.M.

As to the main part of the volume, we are able to compliment Mr. Cook on having brought together a number of examples which are likely to prove useful, especially to teachers. The examples show very considerable variety, those on identities being particularly noteworthy. At the end of each exercise stands a "model solution" which will no doubt prove useful to the student; but what does Mr. Cook mean by saying in one such solution (p. 143) that any three numbers that satisfy the relation $a^2+b^2=c^2$ may be expressed in the form $3n$, $4n$, $5n$? We trust that, should the book reach a second edition, as it doubtless will, Mr. Cook will either dispense with the introduction altogether, which we should be inclined to consider the better plan, or at least remove from it the faults in method to which we have made objection. The good qualities possessed by the main part of the book—the examples themselves—would then render the volume one of undoubted value alike to students and teachers of elementary algebra.

R. E. A.

The Student's Hand-book to the Microscope: a Practical Guide to its Selection and Management. By A Quekett Club Man. (London: Roper and Drowley, 1887.)

ALTHOUGH hand-books and practical guides to the use of the microscope are by no means scarce, this little volume will be welcome to many. It more completely, and in a much smaller compass, meets the precise wants of the beginner who intends to acquire a practical knowledge of the use of the microscope, than the majority of kindred treatises. But it aims only at elementary instruction in the use of the instrument and its accessories. The author does not burden the eager and ambitious amateur who has just become possessed of, or is just about to obtain, a microscope, with the complexities of collecting, preserving, dissecting, preparing, and mounting. There can be no doubt that to obtain a fair initial mastery of a good instrument, with powers up to a quarter-inch objective, and to become facile in the use of all the apparatus which these may involve, for illuminating, polarizing, &c., and, in short, in putting to its best and highest use such a microscope, is by far the better course. To become hastily acquainted with the microscope and its adjuncts, and then to be diverted by elaborate processes for preparing and mounting, is not the surest way to increase the number of skilled and competent masters of the modern microscope. The Quekett Club Man is evidently practical, and sees this. He confines himself to a concise and useful statement, aided by illustrations, of what the microscope is and how its various accessories may be employed.

The author does not claim to take the student into any of the intricacies of high-power work, nor, save in an incidental way, to call attention to the newest microscopy. This is consistent; but we regret that the new and only accurate terminology is not employed. "Numerical aperture," briefly explained, would have been wiser than "angle of aperture," with no comment of any moment as to its relatively unscientific nature. Nor are we quite convinced that, although the author did not hold it to be within his scope to discuss, or even indicate the existence of, "apochromatic lenses," he was as helpful to the uninitiated as he might have been, by not indicating the existence of "compensating eye-pieces"; for both in English and German microscopes, with *any* good objec-

tives, they give better results than the majority of Huyghenian eye-pieces.

We close the book, nevertheless, feeling that it will be an acquisition to many who are without information, and want it, as to how to use the microscope.

A Sketch of Geological History, being the Natural History of the Earth and of its Pre-Human Inhabitants. By Edward Hull, M.A., LL.D., F.R.S. (London: C. W. Deacon and Co., 1887.)

In a prefatory note the publishers of this little book inform the readers that it constitutes the first of a series of volumes devoted to a "Sketch of Universal History." We must congratulate the publishers on having discovered an author with sufficient knowledge, and at the same time with the necessary courage, for coping with such an undertaking. In 148 small pages we have a description of the "original condition of the globe" when it first assumed its present form, followed by sketches of the Archæan and succeeding periods of the earth's history; the whole concluding with a retrospect, which reads like the moral of a fable. The work, it is believed, will form an appropriate introduction to three similar volumes in which the modern history of the world is sketched. The book before us is a marvel of condensation; but in reading it we feel like the unfortunate individuals who are compelled to support life on lozenges composed of "Liebig's Extract."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.

[The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.

Politics and the Presidency of the Royal Society.

I THINK that you have done the scientific world a great service in pointing out, in language to which it seems to me no one can take exception, the inconveniences which may arise from the President of the Royal Society occupying a seat in Parliament.

No one will, I think, contest the fact that the Royal Society occupies a unique place in our social organization. It differs from all other Societies in constitution, temperament, and tradition. To persons unacquainted with its working, its method of procedure often seems deliberate and formal to a fault. To those who take part in its work it is obvious that its intellectual freedom is absolutely unrestrained, and that, subject to such mistakes as no human institution can claim exemption from, its impartiality and independence of judgment are absolutely unfettered. This arises from the fact that it is a picked body of men of the most diverse mental attitudes, who owe their association to nothing but their own exertions, and who are in the habit of expressing themselves with the utmost frankness on subjects of common interest discussed amongst themselves.

With the general body of Fellows the Council, from the rapidity with which it is changed, is in constant touch. It is no great assumption, then, to conclude that the Council when it speaks will have behind it the approval of the Fellows—that is, in point of fact, the sanction of the general scientific opinion of the Empire.

Now, the President of the Royal Society, when he speaks officially, is something more than the President of a learned Society: he is virtually the Speaker of the English scientific world. This being so, his position appears to me to be no small one. It is one which in emergencies may become of paramount importance. And it is this view of his position which disposes me to think that it is desirable that the occupant of such a post should be politically unfettered. I apprehend that this view is shared by Prof. Balfour Stewart when he says: "I grant freely that under ordinary circumstances it is undesirable that the President of the Royal Society should enter the House of Commons." And it is not difficult to see why it is undesirable.

Successive Governments, as is well known, are in the habit of consulting the Royal Society on scientific questions, the solution of which may possibly influence or determine a public policy. To such appeals the Royal Society has hitherto replied to the best of its ability without fear or favour. Will it always have the same freedom when its President is amenable to party discipline? It is only necessary to point to the last session of Parliament to see that there were many occasions when the position of the President on the Government benches would have been a not wholly pleasant one. Much bebadgered Ministers would perhaps have come up to him and have said, You must really make some concession, and the man would be made of iron who would not sometimes yield. Then, having been squeezed himself, he would return to his Council with:—"In the House of Commons the other night a very strong opinion was expressed to me," &c., and the process of squeezing would be transferred to the Council. It is no use saying that these things would not happen; because everyone knows that in actual political life they do. If the President descends from the dignified reserve which hedges him in at Burlington House, he will have to take his chance with the disabilities of the ordinary Parliamentary rank and file.

I cannot therefore resist the conclusion that a President of the Royal Society owes it to himself and to his position to hold aloof from all influences that would impair his freedom, and, as a consequence, that of the Society. His position is one of the few in the country which is unique not merely from its absolute independence of external public influence, but from the sanction which is given to the action of its occupant by internal support. The impossibility of allowing the Judges to sit in the House of Commons is, I suppose, apparent to everyone, and, in my view, every disability in that respect which attaches to them attaches with equal force to the President.

I will only trespass on your space with two further observations.

Prof. Balfour Stewart's last argument is, of course, purely political, and, being so, appears to me to be the one thing needed to demonstrate the unadvisability of any exception to the general principle to which he adheres. He says that the President "has chosen to be an Englishman first and a man of science afterwards." Yes. But—and I trust that no shade of impropriety may be thought to attach to the argument—would he have been as equally acquiescent had the President chosen the political *rôle* of Irishman as his first duty?

Lastly, Prof. Williamson remarks that our President cannot "be supposed to have entered the House as the political representative of the Royal Society." But unfortunately he cannot help himself. He cannot sink his official status. The House of Commons will take note of it just as it does of that of the Lord Mayor and of the Chairman of the Metropolitan Board of Works, who do not sit in Parliament by virtue of their official positions. Yet, being there, they are liable to interpellations with respect to the business of the bodies over which they preside. I do not see why the President of the Royal Society should expect immunity from the same discipline, and the result, it is easy to see, might be extremely embarrassing to the Royal Society, which has other, and in my opinion more constitutional, modes of communicating with the Government, and, if need be, with Parliament.

I say these things not because I like saying them, but because, feeling as I do, I do not think I ought to abstain from saying them. No one has a higher admiration for our President than I have, and no one would less willingly utter a syllable that would give him pain. I rejoice in one aspect of the case, that the University of Cambridge has crowned a great scientific career by a signal honour. But I cannot but feel that the authority and position of the Presidency of the Royal Society belong to a sphere of action infinitely above the conflict of parties, and that they will run a serious risk of impairment when the honoured name of its occupant appears for the first time in modern scientific history in the lists of a party division.

W. T. THISELTON DYER.

Royal Gardens, Kew, November 26, 1887.

As a Fellow of the Royal Society who has sat for many years continuously in the House of Commons, I have read with much interest your article on the above subject, which, from a Royal Society point of view (but not in any sense from a Parliamentary stand-point) is one of very great importance. No reasonable person would for a moment object, I presume, to Prof. Stokes entering Parliament as a politician, if he be one, provided he be very careful to doff at the door of the House of Parliament every vestige of Royal Society representation, and appear there as a private politician to be taken for just what he is worth in that capacity, and no more. Do not let me be misunderstood: as a man of science he will, even in the House of Commons, receive the personal consideration due to his distinguished personal attainments; and few public assemblies are more ready than that House to give the full value to personal qualities and achievements. But the President of the Royal Society will put that distinguished body, no less than himself, in a thoroughly false position if he presumes to utter there a single sentence in its name. Should I be present—and the same may be said, I trust, of other Fellows—I shall not hesitate to rise instantly and disclaim his pretensions, and declare that he has no more authority than one of the doorkeepers to speak in a political assembly in the name of the Society over which in a purely scientific capacity he presides.

Having a most careful regard to the purity of your columns in respect of everything merely political, I find it very difficult to say much of what I think and feel on this question; but when I consider the depths to which a certain ex-Professor has descended since he seated himself upon the steep and slippery slope of politics, I must very earnestly deprecate any similar proceeding on the part of the highest officer of the Royal Society, in that capacity. In the political arena, I fear, we are on both sides daily getting a lower and lower opinion of our opponents, and I must confess that it is rapidly becoming hard to reconcile with the scientific spirit the rancorous abuse and unreasoning misrepresentation with which we are now too familiar.

But I must not be drawn into either polemics or personality. I must content myself with saying, that, if Conservatives think meanly of Liberal politicians just now, their sentiment is thoroughly reciprocated, and probably more than reciprocated, by those who, like myself, believe we have at heart the true greatness, the lasting tranquillity and the intellectual and social progress of the country. For Heaven's sake let us keep the Royal Society, if not above, at least most distinctly apart from, all political contentions; and, in order that we may do this, let its President, who has now become a professed party politician, either vacate the chair, or make it absolutely clear that on the floor of Parliament he will not presume to speak with any kind or degree of authority in the name of the Society.

I have no idea, Sir, of your political views, but I appreciate your desire to keep the Royal Society politically neutral—aye, politically non-existent—and I hope your timely and courageous warning will not have been given in vain.

I have no care to conceal my name, but the end in view may be best promoted, perhaps, by my merely signing myself,

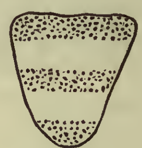
The Vitreous State of Water.

TO-DAY, between 2 and 3 p.m., with the barometer standing at 29 inches, the thermometer a little below 0° C., and the wind north-east, we had for the space of about twenty minutes an interesting fall of hail in this neighbourhood. The stones varied in size from that of a mustard-seed to that of a hemp-seed or thereabouts. Some rain accompanied them, and this became frozen in part on cold exposed surfaces. The stone sill of my study window, which faces nearly north-west, was soon covered in this way with a thin pellicle of ice, which served as a convenient resting-place for the hailstones at a low temperature. I was struck at once with their glassy appearance, and examined a number of them with a pocket lens as they lay on the cold surface of the stone, not having at hand any refrigerating arrangement adjustable to the stage of a microscope. Nor was the latter necessary. The lens showed most distinctly the clear transparency of the glass of which these hailstones consisted, and the vitreous fracture of some which had been broken by impact. Watching them as they lay, one saw minute nests of crystals form, in some cases in a peripheral zone, extending gradually inwards; but in the majority of instances the crystallization began in the centre of the ice, and gradually extended in a beautiful crystal growth more or less through the mass.

There would seem to be no room left for doubt that this crystal-building process (sometimes in bands, sometimes in confused nests of crystals) was a simple case of devitrification—as distinct a case, one may almost say, as the well-known devitrification on a larger scale which is clearly exhibited by some glassy slags. The fact of lying on a surface below 0° C., and undergoing devitrification instead of liquefaction, seems to lend direct support to the theory of *latent heat of the vitreous state*, which I have ventured elsewhere to propound (see NATURE, vol. xxxvi. p. 77).

I may add that last July, in a much heavier hailstorm in the Trent Valley, I noticed a very great number of hailstones, many of them as large as a moderate-sized hazel-nut, and peg-top shaped, with a zonal or banded structure thus:—



The layers or zones were alternately transparent and opaque (apparently crystalline), but in this case the temperature caused them to melt away without allowing a good opportunity for observation of any devitrification of the glassy portions. To-day Nature has performed the experiment suggested in my previous letter, and the result is found to accord with the theory.

A. IRVING.

Wellington College, Berks, November 18.

The Bagshot Beds.

IT may interest some of your readers to know that I recently obtained some casts of fossils from the Bagshot Sands of the Newbury district, from which, with one doubtful exception ("Survey Memoir," vol. iv. p. 330), they have not, I believe, hitherto been recorded. The fossils are of the nature of ferruginous casts, and were found in a sand-pit about one-third of a mile south-east of the London lodge of Highclere Park, mapped by the Survey as Lower Bagshot. They consist both of univalves and bivalves, and four or five genera are represented. They resemble, both in appearance and mode of occurrence, the fossils found in the Upper Bagshot of the Bagshot district; and the sands in which they occur have a strong resemblance to the

sands of that division. To whatever division, however, of the Bagshots these beds may be assigned eventually, the occurrence of fossils in them is, I think, worthy of record.

53 Warwick Square, November 25. R. S. HERRIES.

The Ffynnon Beuno and Cae Gwyn Caves.

SINCE writing my note, as published in NATURE of November 3, p. 7, I have paid another visit to the British Museum, and seen a second implement from the Denbighshire caves, presented by Dr. Hicks and Mr. Luxmore. It is a small and highly-finished scraper, exactly agreeing with the Neolithic scrapers of Icklingham and Mildenhall, and with small scrapers found in caves of confessedly very late date. This scraper is quite sufficient to condemn any pre-Glacial theory, and it enables me to emphasize my former remark that the cave contents, instead of belonging to the earliest Palæolithic class, belong to the *very latest.* I do not believe that a similar scraper has ever been found in any *really old, or even moderately old, Palæolithic river gravel.* Such scrapers were only made in the most recent of Palæolithic times.

Mr. G. H. Morton is not justified in his remark (Nov. 10, p. 32) that my former letter afforded "a remarkable instance of rushing into print and giving an opinion on a subject with which the writer was unacquainted," for I have studied the drifts of Wales for twenty years, and during that time I have never failed to make one or two visits a year to Wales. I have also examined nearly every cave in North and South Wales, and handled the shovel and pickaxe myself. From the experience I have obtained during this time, I say the drift in front of the Denbighshire caves is *not in its original position,* but *distinctly and obviously relaid;* and I even doubt whether before it was relaid it was a true Glacial gravel at all.

I will "read up the literature of the subject" if I get time: in the meantime there is no great harm done in expressing an opinion from a study of some of the real objects, even if that opinion is "not worth anything" and "of no consequence," as Mr. Morton concludes. WORTHINGTON G. SMITH.

Meteor.

ON Tuesday night, November 15, a wonderfully fine meteor was seen at Falmouth, and being out star-gazing at the time, I was fortunate enough to see it. I was looking towards that part of the Milky Way between Auriga, Perseus, and Cassiopeia, when suddenly a curved train of light flashed out; but, instead of just going away, it remained visible for quite eight seconds; meanwhile the lower extremity burst into a brilliant mauve "cone" of light, about a quarter the size of the full moon. So bright was it that it lit up the roadway, quite overpowering the lamps.

It was a grand sight, and I sincerely hope other eyes than mine saw it. B. TRUSCOTT.

4 Alma Crescent, Falmouth.

MODERN VIEWS OF ELECTRICITY.[1]

PART III.—MAGNETISM.

V.

WE next proceed to consider electricity in a state of *rotation.* What happens if we make a whirlpool of electricity? Coil up a wire conveying a current, and try. The result is it behaves like a magnet: compass-needles near it are affected, steel put near it gets magnetized, and iron nails or filings get attracted by it—sucked up into it if the current be strong enough. In short, it *is* a magnet. Not of course a permanent one, but a temporary one, lasting as long as the current flows. It is thus suggested that magnetism may perhaps be simply electricity in rotation. Let us work out this idea more fully.

First of all, one may notice that everything that can be done with a permanent magnet can be imitated by a coiled wire conveying a current. (It would not do altogether to make the converse statement.) Float a coil attached to a battery vertically on water, and you have a compass-needle: it sets itself with its axis north and south. Suspend two coils, and they will attract or repel or turn each other round just like two magnets.

As long as one only considers the action of a coil at some distance from itself, there is no need to trouble about the shape of the particular magnet which it most closely simulates; but as soon as one begins to consider the action of a coil on things close to it, it is necessary to specify the shape of the corresponding magnet.

If the coil be a long cylindrical helix like a close-spired corkscrew, as in Fig. 16, it behaves like a cylindrical magnet filling the same space. But if the coil be a short wide hank, like a curtain-ring, it behaves again like a cylindrical magnet, but one so short that it is more easily thought of as a disk. A disk or plate of steel magnetized with one face all north and the other face all south can be cut to imitate any thin hank of wire conveying a current. It will be round if the coil be round, square if it be square, and irregular in outline if the coil be irregular.

There is no need for the coil to have a great number of turns of wire except to increase its power: one is sufficient, and it may be of any shape or size. So when we come to remember that every current of electricity must necessarily flow in a closed circuit, one perceives that *every current of electricity is virtually a coil of more or*

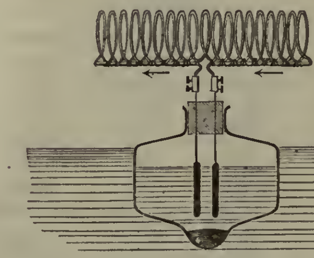


FIG. 16.—Floating battery and helix acting as a compass-needle.

less fantastic shape, and accordingly imitates some magnet or other which can be specified. Thus we learn that every current of electricity must exhibit magnetic phenomena: the two are inseparable—a very important truth.

There is one detail in which the magnetized disk and the coil are not equivalent, and the advantage lies on the side of the coil: it has a property beyond that possessed by any ordinary magnet. It has a penetrable interior, which the magnet has not. For space outside both, they simulate each other exactly; for space inside either, they behave differently. The coil can be made to do all that the magnet can do; but the magnet cannot in every respect imitate and replace the coil: else would perpetual motion be an every-day occurrence.

Now I want to illustrate and bring home forcibly the fact that there is something rotatory about magnetism—something in its nature which makes rotation an easy and natural effect to obtain if one goes about it properly. One will not observe this by taking two magnets: one will see it better by taking a current and a magnet, and studying their mutual action.

A magnet involves, as you know, two poles—a north and a south pole—of precisely opposite properties: it may be considered as composed of these two poles for many purposes; and the action of a current on a magnet may be discussed as compounded of its action on each pole separately. Now how does a current act on a magnetic pole? Two currents attract or repel each other; two poles attract or repel each other; but a current and a pole exert a mutual force which is neither attraction nor repulsion: it is a rotatory force. They tend neither to approach nor to recede; they tend to revolve

[1] This Part is an expansion of a lecture delivered at the London Institution on January 5, 1885. Continued from p. 13.

round each other. A singular action this, and at first sight unique. All ordinary actions and reactions between two bodies take place in the line joining them: the forces acting between a current and a pole act exactly at right angles to the line joining them.

Helmholtz long ago (in 1847) showed that the conservation of energy could only be true if forces between bodies varied in some way with distance and acted in the line joining them. Now here is a case where the forces are not in the line joining the bodies, and accordingly the conservation of energy is defied: the two things will revolve round each other for ever. This affords and has afforded a fine field for the perpetual motionist; and if only the current would maintain itself without sustaining power, a perpetual motion would in fact be attained. But this after all is scarcely remarkable, for the same may be said of a sewing-machine or any other piece of mechanism: if only it would continue to go without sustaining power it would be a perpetual motion. Attend to pole and current only, and the energy is *not* conserved, it is perpetually being wasted; but include the battery as an essential part of the complete system, and the mystery disappears: everything is perfectly regular.

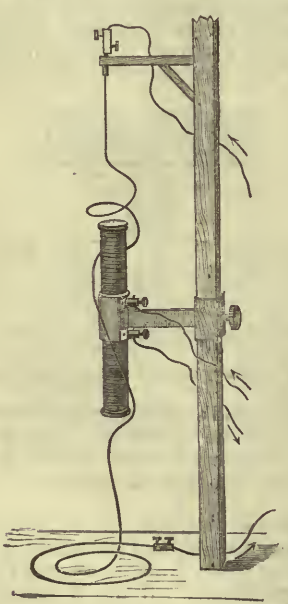

Fig. 17.—A long flexible conductor twisting itself into a spiral round a powerful bar-magnet.

The easiest way perhaps of showing the rotation of a conductor conveying a current round a magnetic pole is to take an 8-feet-long piece of gold thread, such as military officers stitch upon their garments, and hanging it vertically supply it with as strong a current as it will stand. Then bring near it a vertical bar-magnet, and instantly you will see the thread coil itself into a spiral, half of it twisting round the north end of the bar, and half twisting the other way round the south end (Fig. 17).

If the magnet were flexible and the conductor rigid, the magnet would in like manner coil itself in a spiral round the current: the force is strictly mutual. A rigid magnet put near a stiff conductor shows only the last remnants of this action: it sets itself at right angles to the wire, and approaches its middle to touch it, but that is all it can do.

The experiment with the flexible gold thread is simple, satisfactory, and striking, but the rotatory properties connected with a magnet may be illustrated in numbers of other ways. Thus, pivot a disk at its centre, and arrange some light contact to touch its edge, either at one point or all round, it matters not; then supply a current to disk from centre to circumference, and bringing a bar-magnet near it along its axis, or, better, two bar-magnets, with

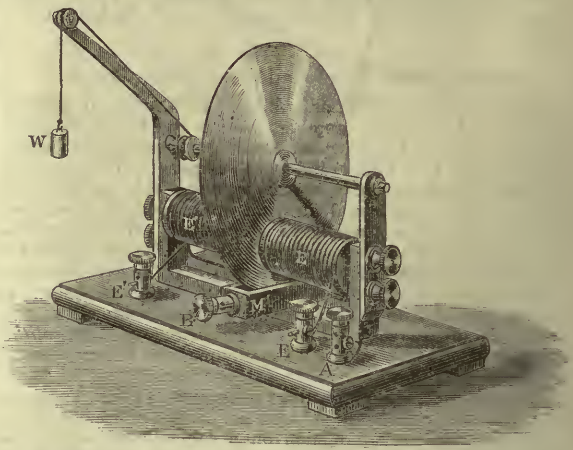

Fig. 18.—Pivoted disk with radial current, revolving in a magnetic field and winding up a weight. The current is supplied to the axle by screw A, and leaves the rim by mercury trough M. The same apparatus obviously serves to demonstrate currents induced by motion; both directly and by the damping effect.

opposite poles one on each side, near the contact place of the rim, the disk at once begins to rotate (Figs. 18 and 19).

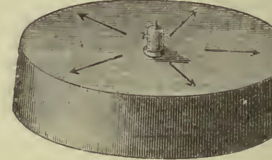

Fig. 19.—Another pivoted disk with flange to dip into liquid so as to make contact all round its rim. It rotates when a magnet is brought above or below; or even in the field of the earth.

Instead of a disk one may use a single radius of it, viz. a pivoted arm (Fig. 20) dipping into a circular trough of mercury; or we may use a light sphere rolling on two

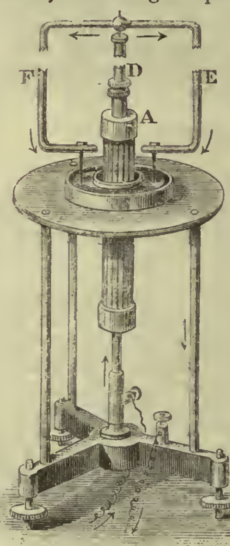

Fig. 20.—A couple of radii of the above disk provided with points to dip into mercury, and rotating constantly under the influence of the steel magnet A.

concentric circular lines of railway (Gore's arrangement, Fig. 21). In every case rotation begins as soon as a magnet is brought near.

Nor is the revolving action confined to metallic conductors and to true conduction. Liquids and gases, although they convey electricity by something of the

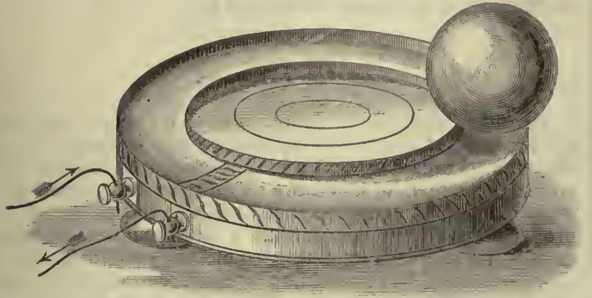

Fig. 21.—Gore's circular railway. The light spherical metal ball revolves round the two concentric metal hoops or rails whenever it is made to convey a current between them in a vertical magnetic field.

nature of convection, are susceptible to rotation in a precisely similar manner.

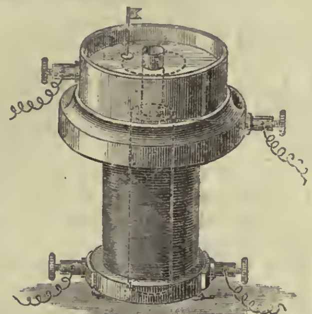

Fig. 22.—Rotation of a liquid disk conveying a radial current in a vertical magnetic field.

To show the rotation of liquid conductors under the influence of a magnet, take a circular shallow trough of

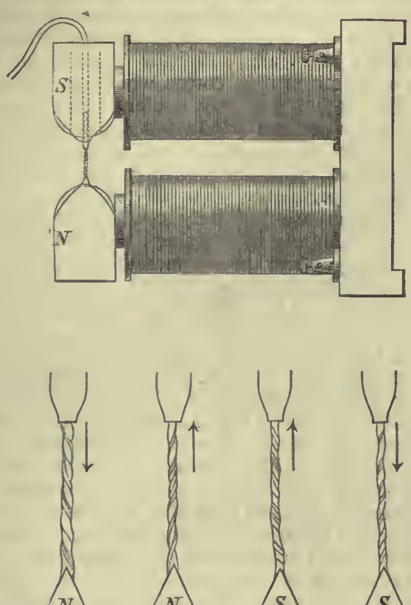

Fig. 23.—A falling stream of liquid conveying a current between two magnetic poles, and being thereby twisted into a spiral. (Copied from a paper in Phil. Mag. by Dr. Silvanus Thompson).

liquid, supply it with electrodes at centre and circumference, and put the pole of a magnet below it. The liquid at once begins to rotate, and by using a magnet and current of fair strength can easily be made to whirl so fast as to fly over the edge of the trough (Fig. 22). The experiment is plainly the same as Fig. 19, except that a liquid disk is used in place of a solid one. Or, again, it may be considered the same as Fig. 20. Reverse the magnet, and the rotation is rapidly reversed.

Another method is to send a current along a jet of mercury near a magnet and note the behaviour of the jet. It twists itself into a flat spiral as shown in Fig. 23.

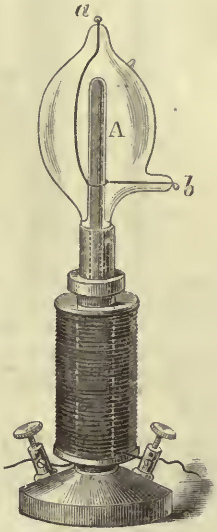

Fig. 24.—Induction coil discharge from *a* to *b* through rarefied gas, rotating round a glass-protected magnetized iron rod.

The rotation of a gas discharge is most commonly illustrated by an arrangement like Fig. 24, where the terminals of the induction coil are connected to the rarefied gas respectively above one pole and round the middle of a magnetized bar. If the discharge can be got to concentrate itself principally down one side, the line of light so formed is seen to revolve.

Action between a Magnet and an Electric Charge in Relative Motion.

From all this it is not to be doubted that a charged pith ball moving in the neighbourhood of a magnet is subject to the same action. There is no known action between a magnet and a *stationary* charged body, but directly either begins to move there is an action between them tending to cause one to rotate round the other. It is true that for ordinary speeds of motion this force is extremely small; but still it is not to be doubted that if a shower of charged pith balls or Lycopodium granules are dropped on to a magnet pole, they will fall, not perfectly straight, but slightly corkscrew fashion. And again, if a set of charged particles were projected horizontally and radially from the top of a magnet, their paths would revolve like the beams of a lighthouse. And if by any means their paths were kept straight, or deflected the other way, they would exert on the magnet an infinitesimal "couple," tending to make it spin on its own axis.

Conversely, if a magnet were spun on its axis rapidly by mechanical means, there is very little doubt but that it would act on charged bodies in its neighbourhood, tending to make them move radially either to or from it. This, however, is an experiment that ought to be tried; and the easiest way of trying it would be to suspend a sort of electrometer needle, electrified positive at one end and negative at the other, near the spinning magnet, and to look for a trace of deflection—to be reversed when the spin is reversed. A magnet of varying strength might be easier to try than a spinning one.

Rotation of a Magnet by a Current.

The easiest way to show the actual rotation of a magnet is to send a current half way along it and back

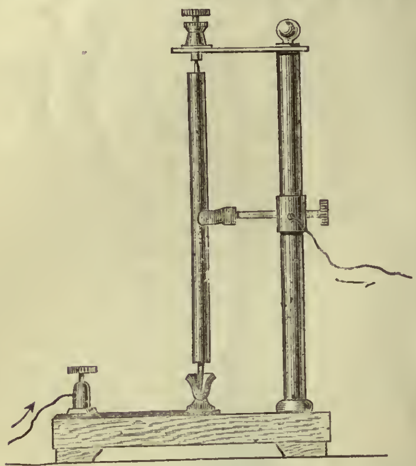

FIG. 25.—Round bright steel bar-magnet pivoted at its ends, spinning rapidly on its axis under the influence of a current supplied to either the bottom or top pivot, or both, and removed near the middle by a scrap of tinfoil lightly touching it.

outside. Thus, take a small, round, polished steel bar-magnet with pointed ends, pivot it vertically, and touch it steadily with two flakes or light pads of tin-foil, one

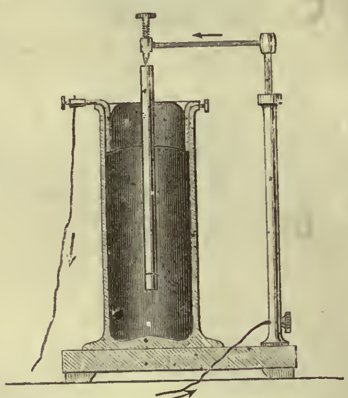

FIG. 26.—Another mode of exhibiting the same thing as Fig. 25. The magnet is loaded so as to float upright in mercury.

near either end and one near the middle; supply a current by these contact pieces, and the magnet spins with great rapidity. Reverse the current, and it rotates

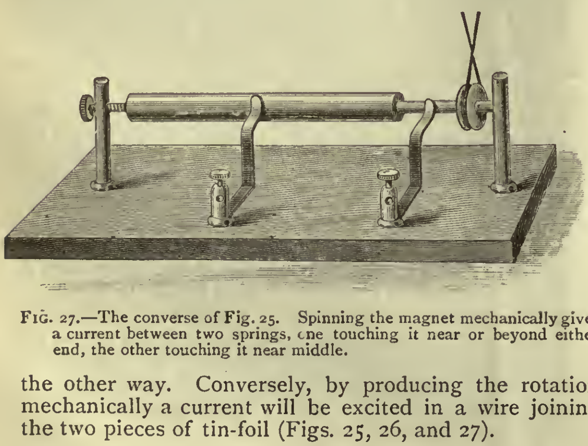

FIG. 27.—The converse of Fig. 25. Spinning the magnet mechanically give a current between two springs, one touching it near or beyond eithe end, the other touching it near middle.

the other way. Conversely, by producing the rotation mechanically a current will be excited in a wire joining the two pieces of tin-foil (Figs. 25, 26, and 27).

Many more variations of the experiment could be shown, but these are typical ones, and will suffice. They all call attention to the fact that a magnet, considered electrically, is a rotatory phenomenon.

Ampère's Theory.

The idea that magnetism was nothing more nor less than a whirl of electricity is no new one—it is as old as Ampère. Perceiving that a magnet could be imitated by an electric whirl, he made the hypothesis that an electric whirl existed in every magnet and was the cause of its properties. Not of course that a steel magnet contains an electric current circulating round and round it, as an electro-magnet has: nothing is more certain than the fact that a magnet is not magnetized as a whole, but that each particle of it is magnetized, and that the actual magnet is merely an assemblage of polarized particles. The old and familiar experiment of breaking a magnet into pieces proves this. Each particle or molecule of the bar must have its circulating electric current, and then the properties of the whole are explained.

There is only one little difficulty which suggests itself in Ampère's theory—How are these molecular currents maintained? Long ago a similar difficulty was felt in astronomy—What maintains the motions of the planets? Spirits, vortices, and other contrivances were invented to keep them going.

But in the light of Galileo's mechanics the difficulty vanishes. Things continue in motion of themselves until they are stopped. Postulate no resistance, and motion is essentially perpetual.

What stops an ordinary current? Resistance. Start a current in a curtain ring, by any means, and leave it alone. It will run its energy down into heat in the space of half a second or so. But if the metal conducted infinitely well there would be no such dissipation of energy, and the current would be permanent.

In a metal rod, electricity has to pass from atom to atom, and it meets with resistance in so doing; but who is to say that the atoms themselves do not conduct perfectly? They are known to have various infinite properties already: they are infinitely elastic, for instance. Pack up a box of gas in cotton-wool for a century, and see whether it has got any cooler. The experiment, if practicable, should be tried; but our present experience warrants us in assuming no loss of motion among the colliding atoms until the contrary has been definitely proved by experiment. To all intents and purposes *certainly* atoms are infinitely elastic: why should they not also be infinitely conducting? Why should dissipation of energy occur in respect of an electric current circulating wholly inside an atom? There is no known reason why it should. There are many analogies against it.

How did these currents originate? We may as well ask, How did any of their properties originate? How did their motion originate? These questions are unanswerable. Suffice it for us, there they are. The atoms of a particular substance—iron for instance, or zinc—have an electric whirl of certain strength circulating in them as one of their specific physical properties.

This much is certain, that the Ampèrian currents are not producible by magnetic experiments. When a piece of steel or iron is magnetized, the act of magnetization is not an excitation of Ampèrian current in each molecule—is not in any sense a magnetization of each molecule. The molecules were all fully magnetized to begin with: the act of magnetization consists merely in facing them round so as to look mainly one way—in polarizing them, in fact. This was proved by Beetz long ago; I will not stop to explain it further, but will refer students to Maxwell.

Ampère's Theory extended by Weber to explain Diamagnetism also.

Let us see how far we have got. We have made the following assertions:—

(1) That a magnet consists of an assemblage of polarized molecules.

(2) That these molecules are each of them permanent magnets, whether the substance be in its ordinary or in its magnetized condition, and that the act of magnetization consists in turning them round so as to face more or less one way.

(3) That when all the molecules are faced in the same direction the substance is magnetically completely saturated.

(4) That if each molecule of a definite substance contains an electric current of definite strength circulating in a channel of infinite conductivity the magnetic behaviour of the substance is completely explained.

But now, supposing all this granted, how comes it that the molecular currents are not capable of being generated by magnetic induction? And if we cannot excite them, are we able to vary their strength?

The answer to these questions is included in the following propositions, which I will now for convenience state, and then proceed to explain and justify.

(5) If a substance possessing these molecular currents be immersed in a magnetic field, all those molecules which are able to turn and look along the lines of force in the right direction will have their currents weakened; but on withdrawal from the field they will regain their normal strength.

(6) If the currents flowing in the conducting channels be feeble or *nil*, the act of immersion of the substance in a magnetic field will reverse them or excite *opposite* currents, which will last so long as the body remains in the field, but will be destroyed by its removal.

(7) The molecular currents so magnetically induced are sufficient to explain the phenomena of *diamagnetism*.

Let us first just recall to mind the well-known elementary facts of current induction. A conducting circuit, such as a ring or a coil of wire, suddenly brought near a current-conveying coil or a magnet, has a momentary current induced in it in the opposite direction to the inducing current—in other words, such as to cause momentary repulsion between the two. So long as it remains steady, nothing further happens; but on withdrawing it another momentary current is induced in it in the contrary direction to that first excited. The shortest way of expressing the facts quite generally is to say that while from any cause the magnetic field through a conductor is increasing in strength a current is excited in it tending to drive it out of the field: the disturbance is only temporary, but whenever the magnetic field decreases again to its old value a reverse flow of precisely the same quantity of electricity occurs. Fig. 28 shows a mode of illustrating the facts. A copper disk is supported at the end of a torsion arm and brought close to the face of an unexcited bar electro-magnet. On exciting the magnet the disk is driven violently away: to be sucked back again, however, whenever the magnetism ceases.

Now, why are all these effects so momentary? What makes the induced current cease so soon after excitation? Nothing but dissipation of energy: only the friction of imperfect conductivity. There is nothing to maintain the current: it meets with resistance in its flow through the metal, and so it soon stops.

But in a perfect conductor like a molecule no such dissipation would occur. Electricity in such a body will obey the first law of motion, and continue to flow till stopped. Destroying the magnetic field will stop an induced molecular current, but nothing else will stop it. Hence it follows that the repulsion experienced is no transitory effect like that in Fig. 28, but is as permanent as the magnetic field which excites and exhibits it.

Thus, then, a body whose molecules are perfectly conducting, but without specific current circulating in them, will behave diamagnetically, *i.e.* will move away from strong parts of the field towards weak ones, and thereby set its length equatorially, just as bismuth is known to do.

Whether this be the true explanation of diamagnetism or not, it is at least a possible one. It is known as Weber's theory.

It does not necessarily follow that the specific molecular currents of a diamagnetic substance are really *nil*; all that is needful is that they shall be weaker than those induced by an ordinary magnetic field. By using an extremely weak field, however, the specific currents need not be quite neutralized, and in such a field the body ought to behave as a very feebly magnetic substance. Such an effect has been looked for (see NATURE, vol. xxxv. p. 484).

One loop-hole there is, however, viz. that every molecule may be so jammed as to be unable to turn round, and such a substance could hardly exhibit any noticeable magnetic properties. The molecules would have got themselves into a state of minimum potential energy, and if jammed therein nothing could be got out of them. The induced currents of diamagnetism would be superposed

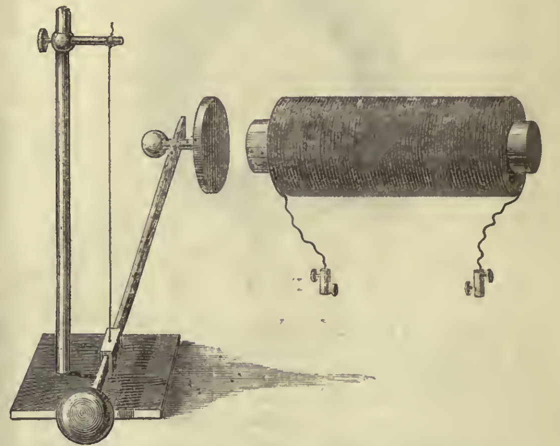

FIG. 28.—Stout disk of copper supported on a horizontal arm near one pole of a bar electro-magnet. The disk is repelled every time the magnet is excited, and is attracted while the magnetism is destroyed.

upon them just as if no initial molecular currents existed. By varying the temperature of such a substance, however, one might expect to alter their arrangement, and so develop magnetic properties in it, just as electrical properties are developed in crystals like tourmaline by heat or by cold.

We are now able clearly to appreciate this much—that the molecular currents needful to explain magnetism are not conceivably excited by the act of magnetization, for they are in the wrong direction. *Induced* molecular currents will be such as to cause repulsion: those which cause attraction must have existed there before, and be merely rotated into fresh positions by the magnetizing force.

Function of the Iron in a Magnet. Two Modes of expressing it.

We can now explain the function of iron, or other magnetic substance, in strengthening a magnetic field. Take a circular coil of wire, Fig. 29, and send a current round it: there is a certain field—a certain number of lines of force—between its faces. Fill the coil with iron, so as to make it a common electro-magnet, and the strength of the field is greatly increased. Why? The common mode of statement likens the magnetic circuit to a voltaic circuit; there is a certain magneto-motive

force, and a certain resistance: the quotient gives the resulting magnetic induction, or total number of lines of force. Iron is more permeable than air—say, 300 times more permeable—and accordingly the resistance of the iron part of the circuit is almost negligible in comparison with that of the air-gap between the poles. Thus a good approximation to the total intensity of field is obtained by dividing the magneto-motive force by the width of the air-gap; or more completely and generally by treating the varying material and section of a magnetic circuit just as the varying material and section of a voltaic circuit is treated, and so obtaining its total resistance. Iron is thus to be regarded as a magnetic conductor some 300 times better than air.

This mode of regarding the case is undoubtedly simple and convenient, but it is not the fundamental mode. If we look at it less with a view to practical simplicity than with the aim of seeing what is really going on, we shall express it thus:—

Before the iron was inserted in the coil there were a certain number of circular lines of force inside it due to the current alone. A piece of common iron, although

FIG. 29.

full of polarized molecules, has no external or serviceable lines of force: they are all shut up, as it were, into little closed circuits inside the iron. But directly the iron finds itself in a magnetic field some of these open out, a chain of polarized molecules is formed, and the lines due to its molecular currents add themselves to those belonging to the current of the magnetizing helix.

Thus our ring electro-magnet has now not only its own old lines of force, but a great many of those belonging to the iron which have sympathetically laid themselves alongside the first.

The end result of either mode of regarding the matter is of course the same—the lines of force between the poles are increased in number by the presence of iron; but whereas, in the first-mentioned mode of treatment, the fact of permeability had to be accepted unexplained, in the second nothing is unexplained except the fundamental facts of the subject, such as the reason why currents tend to set themselves with their axes parallel, and other matters of that sort.

Electrical Momentum once more.

There is just one point which I must stop here to call attention to. The theories of magnetism and diamagnetism, which I have given according to Ampère, Weber, and Maxwell, require as their foundation that in a perfect conductor electricity shall obey the first law of motion—shall continue to flow until stopped by force. But the property of matter which enables it to do this is called *inertia*; the law is called the law of inertia; and anything which behaves in this way must be granted to possess inertia.

It would not do to deduce so important a fact from a yet unverified theory; but at least one must notice that it is essentially involved in Ampère's theory of magnetism. It is the only theory of magnetism yet formulated, and it breaks down unless electricity possesses inertia.

Nevertheless it is a fact that an electro-magnet does not behave in the least like a fly-wheel or spinning-top: there is no momentum mechanically discoverable. Supposing this should turn out to be strictly and finally true, we must admit that a molecular electric current consists of two equal opposite streams of the two kinds of electricity: one must begin to regard negative electricity not as merely the negation or defect of positive, but as a separate entity. Its relation to positive may turn out to be something more like that of sodium to chlorine than that of cold to heat.

I said that no effect due to electric inertia was *mechanically* discoverable, but that is perhaps too sweeping a statement. Think of a couple of india-rubber pipes tied together so as to form a double tube, and through each propel a current of water, one in an opposite direction to the other. Although the double current has no gyrostatic properties, yet the water exhibits momentum, even when the current is quite steady, by its effect on kinks and bends and curves in the tube: these all tend to straighten or smooth themselves out, and the tube if quite free would become a perfect circle.

Precisely the same effect can be observed with a flexible conducting wire or gold thread. Throw a loop of very light flexible thinly-covered stranded wire at random on a glass slab, and pass a strong current through it: it will tend to round off its sharp corners, open out its tangled loops, and do its best to become a perfect circle; and this quite independently of the earth's field, in accordance with the principle numbered 3 on page 8. It will be at once objected that this effect, in the case of the wire, is due to something going on in the medium surrounded by it, and not simply to the inertia of anything in the conducting channel itself, as in the water case. The objection is, of course, perfectly valid, but nevertheless the effect is one worth bearing in mind; and its ultimate explanation may lead us to postulate inertia quite as essentially though not so superficially as the crude hydraulic analogy suggests.

So long as one considered the flow of electricity in ordinary conductors, we could partially avoid the question of inertia by considering it urged forward at every point with a force sufficient to overcome the resistance there and no more; but though this explained the shape of the stream-lines (Fig. 15) yet it did not suffice to render clear the phenomena of self-induction—the lag of the interior electricity in a wire behind the outside until definitely pushed; and still more its temporary persistence in motion after the pushing force has ceased.

But, now that we are dealing with perfect conductors with no pushing force at all, the persistence of molecular currents without inertia, or an equivalent property so like it as to be rightly called by the same name at present, becomes inexplicable. True, the molecular currents are as yet an hypothesis; and that is the only loop-hole out of a definite conclusion.

OLIVER J. LODGE.

(To be continued.)

DISCOVERY OF DIAMONDS IN A METEORIC STONE.

IN a Russian paper of October 22 last appears a preliminary report of the examination by Latschinof and Jerofeief, Professors of Mineralogy and Chemistry respectively, of a meteoric stone weighing 4 lbs., which fell in the district of Krasnoslobodsk, Government of Pensa, Russia, on September 4, 1886.

In the insoluble residue small corpuscles showing traces of polarization were observed; they are harder than corundum, and have the density and other characters

of the diamond. The corpuscles are said to amount to 1 per cent. of the meteoric stone.

Carbon, in its amorphous graphitic form, has been long known as a constituent of meteoric irons and stones; lately, small but well-defined crystals of graphitic carbon having forms often presented by the diamond, were described in our columns as having been found in a meteoric iron from Western Australia. If this supplementary discovery be confirmed, we may at last be placed on the track of the artificial production of the precious stone.

NOTES.

On Tuesday afternoon an important meeting was held in the Town Hall, Manchester, in support of the National Association for the Promotion of Technical Education. A powerful and most interesting address was delivered by Prof. Huxley. Afterwards, in accordance with a resolution moved by Sir H. E. Roscoe, and seconded by Sir W. H. Houldsworth, the meeting appointed an influential Committee to consider the proposals communicated by the National Association for the Promotion of Technical Education, and to take action thereon. Now that the vital importance of the subject is beginning to be understood in the district, there can be little doubt that Manchester will soon be supplied with a thoroughly sound and adequate system of technical instruction. The residuary legatees under the will of the late Sir Joseph Whitworth have just presented to the town a plot of land, called Potter's Park, which they have bought for £47,000. On a part of this land it is proposed that the following institutions shall be erected: (1) an appropriate Institute of Art, with galleries for paintings, for sculpture and moulded form, and for architectural illustration; (2) a comprehensive Museum of Commercial Materials and Products; (3) a Technical School on a complete scientific and practical scale. Much money will have to be provided before this scheme can be fully carried out, but in so great a centre of manufacturing and commercial energy the necessary funds should be raised without serious difficulty. The managers of the late Manchester Exhibition, like the Whitworth legatees, are vigorously supporting the movement, and their example will certainly be extensively followed. The progress made at Manchester is most satisfactory, and there are also many signs of an advance in the right direction at Liverpool and Newcastle.

The latest news from Mr. John Whitehead is that he has returned from Palawan with a rich collection, especially in birds, of which he believes that he has obtained over eighty species not previously recorded from the island, and a large number of migrants. Palawan is an interesting place for a naturalist, as it lies so near the Philippine Archipelago, and yet contains a very strong Bornean element. Mr. Whitehead proposes shortly to make another ascent of Kina Balu Mountain, where last spring he obtained nineteen new species of birds, described by Mr. Bowdler Sharpe in the *Ibis* for October.

Letters have recently been received from Mr. H. O. Forbes, who is now at Granville in British New Guinea. He has not recovered from the overwhelming disaster at Batavia, when the whole of the *matériel* for his explorations was lost by the upsetting of a boat in the surf, but his spirits and those of his brave wife appear indomitable, and he hopes yet to proceed into the interior of New Guinea. He remarks that the Horse-shoe Range of the Astrolabe Mountains is unkown to residents in the island. This is the place whence Mr. Hunstein sent the wonderful birds of Paradise described by Dr. Finsch and Dr. Meyer, but Mr. Forbes says that he cannot find out the position of the range to which Hunstein attached the name. Mr. Forbes states that he has penetrated further inland than any other explorer, but that "no European foot has yet trod any portion of the real Owen Stanley Range." Surely some assistance can be rendered to this good naturalist, who has expended £2000 of his own money in the cause of science, to enable him to prosecute further researches. It only requires a glance at Mr. Forbes's work on the Malay Archipelago to show that he is a worthy follower in the footsteps of Wallace.

At a dinner given by the Library Committee of the Corporation of London on Monday, Prof. Stokes responded for "Science." He said men of science knew how fascinating the pursuit of science was, even apart from its applications. It differed from art, however, in this respect, that when the scientific man had arrived at his result it was in very many cases of such a nature that only comparatively few men, who themselves had been trained more or less in science, could enter into and derive pleasure from it.

The discussion on Sir Frederick Abel's paper on "Accidents in Mines," at the Institute of Civil Engineers, came to a conclusion on Tuesday evening, the debate having extended over four meetings, a number of well-known colliery owners and managers coming up from the country to take part in it. Safety-lamps, gas, coal-dust, winding-gear, and other topics were exhaustively discussed, and it was evident that amongst practical men a considerable difference of opinion exists on many of the questions raised. Sir Frederick having directed attention to the communication in Nature, vol. xxxvi. pp. 437 and 438, Mr. Harries gave further particulars bearing upon the meteorology of colliery explosions. He showed how the popular belief that disasters are always accompanied by a low barometer is fostered by English and foreign newspaper reporters and writers habitually making statements on the subject which cannot be justified by the facts. Very few of the explosions of 1886 and 1887 have been coincident with a low barometer, and out of the list of disasters in the eleven years 1875–85 given by Sir Frederick Abel only 18·75 per cent. of the accidents, and 17·4 per cent. of the deaths, occurred when the mercury was at 29½ inches or below. One half of this small percentage of explosions took place with a low but rapidly rising barometer, and at a time when gas is shown by careful observations to have commenced issuing from the strata. The importance of studying the influence of anticyclones in connection with mining was still further emphasized, as coal-dust is more inflammable and more difficult to moisten when the air is cold and dry than in the time of cyclones, when the air is warm and damp. In the new rooms recently added to the Institute, an interesting series of appliances for use in mines was on exhibition, a number of safety-lamps of different patterns, oil and electric, the Fleuss apparatus, Loeb's respirator, safety winding-gear, anemometers, and a collection of photographs of miners actually at work, hewing, timbering, &c., from Mr. Sopwith, Cannock Chase.

Mr. Goschen will deliver his inaugural address as President of the Royal Statistical Society on Tuesday, December 6, when the first ordinary meeting of the present session will be held. The Statistical Society usually holds its meetings at the Royal School of Mines in Jermyn Street; but on the present occasion, as the Council have reason to expect an extra large attendance of the Fellows and their friends, it has been arranged that the meeting shall take place at Willis's Rooms, King Street, St. James's, at the usual hour, 7.45 p.m.

We regret to have to record the sudden death of Dr. Max Schuster, Privat-docent and Assistant in the University of Vienna. His laborious researches on the optical characters of the Felspars are known to every petrologist; and his treatise on the features of Danburite, in its almost painful minuteness of observation and calculation, is one of the seven wonders of modern crystallography. His kindliness of manner, and his enthusiasm,

won him the affection and esteem of all who had the good fortune to know him: by his death, at the early age of thirty, Mineralogy is deprived of the most promising of its investigators.

Dr. Gustav Theodor Fachner, the well-known physicist, died at Leipzig on November 18. He was born near Moscow, on April 19, 1801.

Naturalists have learned with much satisfaction that Mr. William Davison has been appointed to the Curatorship of the Singapore Museum. Mr. Davison's appointment has been objected to on the score that he is a "mere collector," but, even if this were the case, it would scarcely be denied that he is one of the best collectors ever known. Certainly he is without a rival in the present day, and only Wallace or Bates or Clarence Buckley could be named along with him. Such objectors, however, are singularly ignorant of Mr. Davison's career. For thirteen years he was Curator to Mr. Allan Hume, whose private museum was one of the best managed in the world, and he has conducted some of the most important scientific expeditions of modern times. At Singapore he will have the opportunity of completing his explorations in Malacca, which he commenced some ten years ago, when he traversed the whole of the western half of the peninsula, but was not able to penetrate to the mountainous regions of the eastern half. A rich field of discovery awaits him, if we may judge from the collections sent by Mr. Wray to the British Museum from the Larut Range behind Perak. Every naturalist may depend upon the hearty co-operation of Mr. Davison in any branch of science, and we shall expect to see that, in the course of a few years, Singapore possesses one of the most famous natural history collections in the East.

On Saturday last Mr. Francis Galton gave at the South Kensington Museum the first of three lectures on heredity and nurture. Towards the close of the lecture Mr. Galton spoke of the advantages which might be derived from the establishment of a permanent anthropometric laboratory. An anthropometric laboratory is a place where a person may have any of his various faculties measured in the best possible way, at a small cost, and where duplicates of his measurements may be preserved, as private documents for his own future use and reference. Such an institution would contain apparatus both of the simpler kind used for weighings and measurings, and for determinations of chest capacity, muscular strength, and swiftness, and that of a more delicate description, used in what is technically called psycho-physical research, for determining the efficiency of each of the various senses and certain mental constants. Instruction might be afforded to those who wished to make measurements at home, together with information about instruments and the registration of results. An attached library would contain works relating to the respective influences of heredity and nurture. These would include statistical, medical, hygienic, and other memoirs in various languages, that are now either scattered through our different scientific libraries or do not exist in any of them. Duplicates of the measurements, but without the names attached, would form a growing mass of material accessible to statisticians. From conversation with friends, Mr. Galton gathers that the library might fulfil a welcome purpose in becoming a receptacle for biographies and family records, which would be in two classes—the one to be preserved as private documents, accessible only to persons authorized by the depositor; and the other as ordinary books, whether they were in manuscript or in print. Mr. Galton will be grateful for any communications that may show whether sufficient interest really exists to justify a serious attempt to found an Anthropometric Laboratory and Family Record Office, as well as for any helpful suggestions towards the better carrying out of the idea.

Comparing the proceedings of the Anthropological Sections of the British and American Associations for the Advancement of Science, the American journal *Science* decides that the anthropological work done in the English institution is superior to that of the Americans. "We do not mean to say," it states, "that there are no vague theories held by British men of science, or that no eminent work is done by Americans; but the favourite studies of ethnologists as a whole, and as expressed in the subjects of papers presented to the English Association, seem to be of a more general and of a higher scientific character than they are here."

In a recent number of the *Korrespondenzblatt* of the German Society for Anthropology and Ethnology, there is a good account of the archæological explorations which have been carried on near Reichenhall, in the south-eastern part of Bavaria. An ancient cemetery was discovered here some time ago, and no fewer than eighty-five skulls have been found, with some well-preserved skeletons, and a great quantity of weapons and ornaments. The skulls are of the primitive Germanic type, and the skeletons show that the people must have been about the size of the existing population of the Bavarian highlands. Among the treasures which have been recovered is a thin gold coin, evidently an imitation of a Roman coin. This coin probably belongs to the fifth century, and it may have found its way to this part of Germany in consequence of the intimate relations which are known to have existed between the ancient inhabitants of Bavaria and the Langobardi.

An interesting account of a series of experiments upon the so-called alloy between the metals sodium and potassium is given by M. Joannis in the current number of the *Annales de Chimie et Physique*. For some years it has been known that, although in many respects so similar, the e two metals possess a certain affinity for each other, and unite under suitable circumstances to form a liquid amalgam-like substance. M. Joannis has at length shown that a definite compound, NaK_2, is formed with considerable evolution of heat when the fused metals are brought together in the right proportion. In order to prove this fact, thermo-chemical methods were resorted to, liquid mixtures of the composition Na_2K, NaK, NaK_2, and NaK_3 being successively introduced into the calorimeter. The hydrogen liberated by decomposition of the water in the calorimeter was caused to pass first through a perforated platinum plate, and afterwards through a long thin-walled glass spiral, eventually escaping in minute bubbles through the water itself, after becoming reduced to the temperature of the calorimeter. The liquid mixture of metals was gradually introduced by means of an ingenious apparatus consisting of a drawn-out delivery-tube containing the alloy between two layers of protecting naphtha, and which, by means of a valve, could be placed in communication with a reservoir of compressed air, so that, by regulating the valve, a gentle stream of the liquid could be forced out as required. When the calorimetrical experiments were concluded, the amount of alkali was determined in an aliquot part of the water in the calorimeter, and thus the amount of metal used could be arrived at. From the data afforded by these experiments, M. Joannis appears to have conclusively shown that the only stable compound is NaK_2, all others being mixtures of this with excess of one or other of the two metals. It is very satisfactory that a reliable method has at last been found of distinguishing between true compounds and physical mixtures of metals, and rather remarkable that one of the earlier analyses of the most stable combination of sodium and potassium gave as the percentage of potassium 76·5, a number which closely approximates to that required for NaK_2.

Since the Ben Nevis Observatory was opened four years ago, eleven cases of St. Elmo's fire have been recorded. These case

have been examined by Mr. Rankin, first assistant, and compared with the other observations made from thirty hours previous to eighteen hours subsequent to the times of occurrence. It would appear that the phenomenon has almost invariably occurred when the temperature, after having been for some time distinctly above the mean of the season, has been falling for about twenty-four hours. During this time, while the temperature fell, the barometer also continued to fall till within three hours of the time of St. Elmo's fire, and thereafter rose steadily. The wind is west-south-westerly till the barometer falls to the minimum, and then shifts to north-west. The accompanying weather is fog, squalls, and unusually large-sized soft hail. Mr. Rankin further compared the phenomena with the weather charts of the Meteorological Office, with the result that pressure was in all cases highest over the south-west and south of Europe, diminishing, however, gradually towards North-Western Europe, where pressure was comparatively low, with several satellite cyclones skirting the northern coasts of the British Islands. Of the eleven cases, two occurred in September, three in October, four in November, one in January, and one in February.

The Meteorological Report of the Straits Settlements for the year 1886 has been issued. Charts are appended, showing the mean annual elements from 1870 to 1886.

Dr. A. Müttrich has published the twelfth Annual Report of the forest meteorological observations of Germany. The stations now number sixteen, and the observations of temperature, &c., are made in the open, in the forests, and in the crowns of the trees. Monthly and yearly *résumés* are given, but there is no discussion of the results. Special attention is paid to evaporation and rainfall.

Several earthquakes are reported from Carinthia and Styria. On November 14 a shock was felt at Klagenfurt at 10 p.m., which lasted for four seconds. At Bleiburg, as well as over the whole of Carinthia, severe oscillations were noticed. Reports state that shocks occurred at 11 p.m. at Graz and Saldenhofen, and at 4 p.m. at Ostrau-Witkowitz. At Cavaillon and St. Saturnin-lès-Avignon (Vaucluse) oscillations were felt on November 14. At Cavaillon eleven houses were damaged. On November 17, at 8.55 a.m., two severe shocks occurred at Zafferana, near Etna. A severe earthquake, lasting for ten minutes, occurred in Iceland on October 28; at Reikianaes large chasms appeared in the ground.

The second session of the Liverpool Biological Society was opened on October 29, when Dr. J. J. Drysdale, the President, delivered an address on the definition of life as affected by the protoplasmic theory. The Council's Report showed the affairs of the Society to be in a very satisfactory condition, the number of members amounting to 121. At the second meeting of the session, held on November 12, the following papers, dealing with the history of the foundation of the Zoological Station on Puffin Island, Anglesey, were read: account of the foundation of the Station, and of the general work done during the past summer, by Prof. Herdman; report on the land Mollusca, by Alfred Leicester; report on the higher Crustacea, by A. O. Walker; report on the Actiniaria, by J. W. Ellis; report on the Copepoda, by J. C. Thompson; report on the Polyzoa, by J. Lomas.

At a meeting of the Aristotelian Society on November 21, Dr J. McK. Cattell, of the University of Pennsylvania, read a paper on "The Psychological Laboratory of Leipzig." He explained how experimental psychology undertakes to analyze and measure mental phenomena, and advocated the systematic work of the laboratory, both for the education of students and for the advancement of knowledge. An account was then given of the psychological laboratory at Leipzig, founded by Prof. Wundt in 1879, and of the researches which have been undertaken in it, including experiments on the measurement of sensation, the duration of mental processes, attention, memory, and other subjects. The paper was followed by a discussion in which Prof. Bain, Prof. Dunstan, and others took part.

An address on the Army Medical School, delivered some months ago by Sir Henry W. Acland, at Netley Hospital, at the distribution of prizes, has now been published. The author explains that he issues the address because of an opinion recently expressed before a Committee of the House of Commons by the Accountant-General of the Army, to the effect that the Army Medical School might be advantageously dispensed with. Sir Henry hopes that the Accountant-General of the Army may revise his opinion, and propose hereafter to increase the grant and to enlarge the scope and means of the school.

The American Industrial Education Association is about to issue leaflets, giving concise information on points of its work regarding which questions are continually asked. The first leaflet will state compactly what the argument for manual training is.

In a Report just published by the Foreign Office, on the trade of the Nyassa Territories, Mr. Hawes, the newly-appointed Consul, describes the Strophanthus, a climbing plant from which the natives extract a strong poison, and which is beginning to find its way into the London market. It is called by the natives *kombe*, and is found at a low level, and not apparently on high land. The supplies hitherto obtained have been drawn from the right bank of the Shire River below the Murchison Rapids. There is apparently more than one species, or at least variety, the distinguishing feature being a much smaller pod and fewer seeds. At present, information relative to the varieties is scant. It is a strong climbing plant, and is always found in the vicinity of high trees, on which it supports itself. The stem varies in diameter, but has an average of a few inches. It lies on the ground in folds, the branches supporting themselves on the nearest trees. The young branches are in appearance not unlike the elder. The fruit grows in pairs, and has a peculiar appearance, very like a pair of immense horns hanging to a slender twig. It begins to ripen in July, and lasts till the end of September. The native method of preparing the poison is very simple. They first clean the seeds of their hairy appendages, and then pound them up in a mortar until they have reduced them to a pulp. A little water is then added. This is done by using the bark of a tree containing a gummy substance, which helps to keep the poison on the arrow, in the event of its striking against a bone. The poison thus prepared is spread upon the arrow, and allowed to dry; game wounded by arrows poisoned with Strophanthus die quickly. The flesh is eaten without evil effect. The only precaution taken is to squeeze the juice of the baobab bark on the wound made by the arrow, and this counteracts the evil effects of the poison. Buffalo and all smaller game are killed by this poison.

The additions to the Zoological Society's Gardens during the past week include a Cheetah (*Cynælurus jubatus*) from East Africa, presented by Mr. Frederick Holmwood; two White-backed Piping Crows (*Gymnorhina leuconota*) from Tasmania, presented by Mr. C. Sadler; a Crowned Hawk Eagle (*Spizætus coronatus*) from South Africa, presented by Mr. E. A. Hart; two Cereopsis Geese (*Cereopsis novæ-hollandiæ*) from Australia, presented by His Grace the Duke of Northumberland, P.C., K.G.; a Common Crossbill (*Loxia curvirostra*) British, presented by Mr. S. R. Armord; a Knot (*Tringa canutus*) British, presented by Mr. Howard Bunn; two Thunder Fish (*Misgurnus fossilis*) from the Baltic Sea; four Chub (*Leuciscus cephalus*) from British fresh waters, presented by Messrs. Paul and Co.; two Cape Crowned Cranes (*Balearica chrysopelargus*) from East Africa, a Mealy Amazon (*Chrysotis farinosa*) from South America, deposited.

OUR ASTRONOMICAL COLUMN.

Probable New Variables.—Mr. John Tebbutt calls attention in the *Observatory* for November to the double star OΣ 256, one of the components of which appears to be variable; for during the occultation of the star on August 22 the preceding component appeared very distinctly the brighter of the two, whilst Crossley and Gledhill, in their "Hand-book of Double Stars," regard this star as the companion. Struve was apparently the first to draw attention to the probable variability of this star, for whilst he usually estimated the preceding star as the brighter by half a magnitude, Dembowski recorded it as being the fainter by that amount.

Dr. Bauschinger (*Astr. Nach.* No. 2810), finds that a star in Libra, Lam_3 1875, Munich Zones 695—place for 1855·0, R.A. 15h. 4m. 1·5s., Decl. 5° 27′·6 S.—is also probably variable. Lamont gives the star as of the eighth magnitude; Dr. Bauschinger finds it 9·2 m.; it is wanting in the southern Durchmusterung. Dr. Schönfeld writes that he observed the star on two, if not three occasions; once as 10 m. and once as 12 m. It should therefore be added in the *Bonn. Beob.* vol. viii., after −5° No. 4028, as:—

"Var. 15h. 4m. 2·5s., 5° 27′·5 M."

Names of Minor Planets.—Minor Planet No. 268 has received the name of Adorea; No. 270 that of Anahita.

The Spectra of Oxygen and Carbon compared with that of the Sun.—Prof. Trowbridge and Hutchins have presented to the American Academy of Arts and Sciences a paper on the spectra of oxygen and carbon as compared with that of the sun. In the case of the former element, Dr. Henry Draper had convinced himself that there were bright lines in the solar spectrum corresponding to the bright lines of oxygen, whilst his brother, Prof. J. C. Draper, had identified the oxygen with faint dark lines, but the present experimenters conclude that "so far as concerns the spark spectrum in air and the solar spectrum from wave-lengths 3749·8 to 5033·85 they can safely affirm that there is no physical connection between them." They "have photographed the sun's spectrum every day that the sun has shone for nearly five months, without finding a line that could with certainty be pronounced brighter than its neighbours"; the powerful dispersion given by the large concave Rowland grating employed by Messrs. Trowbridge and Hutchins causing the "bright bands to vanish," which Dr. H. Draper thought he had discovered, and which seemed conspicuous with the dispersion he used, whilst it showed at the same time that there was no real correspondence between the oxygen lines and the dark lines Prof. J. C. Draper had identified with them. Lack of sufficient instrumental power had led both of the two earlier observers astray.

With regard to carbon, Messrs. Trowbridge and Hutchins are of opinion "that the fluted spectrum of carbon is an example of the reversal of the lines of a vapour in its own vapour," and they find a striking coincidence in many cases between the spaces separating the fine bright lines of the flutings and dark lines in the solar spectrum, twenty-eight such coincidences being traced within the limit of ten wave-lengths in the fluting at wave-length 3883·7. Their hypothesis as to the origin of the flutings leads them "to conclude that, at the point of the sun's atmosphere where the carbon is volatilized so as to produce the peculiar arrangement of reversals observed, the temperature of the sun approximates to that of the voltaic arc."

Olbers' Comet, 1887.—The following ephemeris for Berlin midnight for this object is in continuation of that given in Nature, vol. xxxvi. p. 588, and vol. xxxvii. p. 37, and is by Herr Tetens (*Astr. Nach.*, No. 2813):—

1887.	R.A. h. m. s.	Decl. ° ′	Log r.	Log Δ.	Brightness.
Dec. 1	15 26 36	7 10·9 N.	0·1594	0·3354	0·84
3	15 32 7	6 34·7			
5	15 37 31	5 59·5	0·1692	0·3417	0·78
7	15 42 49	5 25·1			
9	15 48 0	4 51·6	0·1790	0·3478	0·73
11	15 53 4	4 19·1			
13	15 58 2	3 47·5	0·1890	0·3537	0·68
15	16 2 54	3 16·9			
17	16 7 41	2 47·2 N.	0·1990	0·3593	0·63

The brightness on August 27 is taken as unity.

A Vienna observation of October 21 gives the error of the ephemeris as R.A. + 3s. and Decl. + 0′·2, and this will probably slowly increase.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 DECEMBER 4–10.

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 4

Sun rises, 7h. 50m.; souths, 11h. 50m. 19·6s.; sets, 15h. 51m.: right asc. on meridian, 16h. 42·2m.; decl. 22° 15′ S. Sidereal Time at Sunset, 20h. 44m.

Moon (at Last Quarter on December 8, 3h.) rises, 18h. 39m.*; souths, 2h. 44m.; sets, 10h. 44m.: right asc. on meridian, 7h. 34·0m.; decl. 20° 0′ N.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. and declination on meridian. h. m.	° ′
Mercury..	5 46	10 27	15 8	15 18·9	15 49 S.
Venus	3 20	8 45	14 10	13 36·7	7 36 S.
Mars	0 53	7 8	13 23	11 58·9	2 8 N.
Jupiter	5 56	10 27	14 58	15 18·9	17 25 S.
Saturn	19 57*	3 45	11 33	8 35·1	19 6 N.
Uranus	2 35	8 9	13 43	13 0·6	5 46 S.
Neptune..	15 11	22 52	6 33*	3 45·8	18 5 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

Occultation of Star by the Moon (visible at Greenwich).

Dec.	Star.	Mag.	Disap. h. m.	Reap. h. m.	Corresponding angles from vertex to right for inverted image. ° °
6	7 Leonis	6½	5 18	6 27	59 300

Dec.	h.	
4	11	Mercury in conjunction with and 1° 35′ north of Jupiter.
5	5	Saturn in conjunction with and 0° 51′ north of the Moon.
5	8	Mercury at greatest elongation from the Sun, 21° west.
9	5	Mars in conjunction with and 2° 10′ south of the Moon.

Saturn, December 4.—Outer major axis of outer ring = 44″·3; outer minor axis of outer ring = 14″·2; southern surface visible.

Variable Stars.

GEOGRAPHICAL NOTES.

In the *Bulletin* of the California Academy of Sciences for June, Mr. C. M. Richter re-examines all the data relating to the ocean currents contiguous to the coast of California, with the result that existing charts are in many cases found to be wrong, and that great diversity of opinion exists as to the real character and origin of these currents.

In the new number of the *Mouvement Géographique* the various rumours that have been afloat as to disasters which have happened to Mr. Stanley's Expedition are examined, and, when tested by known facts and the latest trustworthy information from Mr. Stanley himself and his officers, are shown to be without justification.

Mr. Montagu Kerr sailed from London last Thursday for Zanzibar, for the purpose of attempting to cross Africa by a new route. It is a mistake to refer to Mr. Kerr's private expedition as intended for the further "relief" of Emin Pasha. It has nothing whatever to do with Emin Pasha; though, no doubt, Mr. Kerr will shape his course through Masai Land towards Wadelai as his first stage, and may be guided by Emin's advice as to his further course. His main object after reaching Wadelai will be to proceed in a north-westerly direction towards Lake Chad, solving as far as possible by the way the hydrography of the Welle and Shari regions. After exploring around Lake Chad, Mr. Kerr may make for the Niger, though it is possible enough he will go on northwards in the direction of Tripoli. Since his return from his South African journey, Mr. Kerr has been diligently qualifying himself for scientific observation.

The paper on Monday at the Royal Geographical Society was one of unusual originality; it described Mr. A. D. Carey's two years' journey around and across Turkistan and into the north of Tibet. Mr. Carey, who was accompanied by the well-known Central Asiatic traveller, Mr. Dalgleish, describes so many new features that it is impossible to follow his route throughout on any map. Although his route coincided to some extent with those of Prejevalsky, he has been able to supplement the Russian traveller's observations in many directions. Mr. Carey, starting from Leh in Ladak, crossed the western part of Tibet and the western continuation of the Altyn Tagh, to Kiria in the south-west corner of the great Tarim Desert. Thence along the Khoten River he reached the Tarim, the course of which he followed, with excursions to various places on the route, as far as Lob Nor. The hydrography of this interesting river Mr. Carey has helped considerably to clear up. Some time was spent about the Lob Nor region, and then Mr. Carey, amid many difficulties, endeavoured to penetrate as far as possible into Tibet; but as his time was limited he did not succeed in getting further than the Ma Chu, about half-way between the Kuen Lun and the Tangla Range. But in his wanderings to and fro in the great marshy and desert plain that lies between the Altyn Tagh Mountains and the Kuen Lun, he has added something to our knowledge of one of the most interesting regions of Central Asia. From the Ma Chu, Mr. Carey struck almost direct northwards by Sachu to Hami, across the Gobi Desert. Then by a great sweep he traversed the northern border of Turkistan, by Turfan, Karashahr, Kuchir, Aksu, and Yarkand, back to Leh, two years after he left it. As he says, he thus completed the circuit of Chinese Turkistan, and, Kashgar excepted, visited every important place in it. The chief characteristic of the country is its extreme poverty. It may be described as a huge desert fringed by a few small patches of cultivation. The only really good strip of country of considerable size is the western portion, comprising Kargalik, Yarkand, and Kashgar. To the north a succession of very small oases extends along the foot of the Tian Shan Mountains, the stretches of intervening desert becoming longer as the traveller goes further to the east. The eastern extremity of the province is desert pure and simple, and so is the southern extremity as far west as Kiria, with the exception of the small oases of Charchand and Chaklik. The central portion is chiefly desert, except along the Tarim and in the Lob Nor region. Mr. Carey gives some useful notes on the different classes of people he met with, and occasionally a jotting on the natural history of the region. But the chief scientific result of Mr. Carey's journey is the excellent map which Mr. Dalgleish carefully plotted every day, and which covers many sheets; it is being reduced, and will be published by the Royal Geographical Society.

The correspondence from Major Barttlet, Mr. Stanley's second in command, from his station on the Aruwimi, shows that all is going well, and that if there are any dangers they will be due to the Arabs, and not to the natives. For the many rumours of disaster to the Expedition there is no foundation in fact; there is positively no news from Mr. Stanley since he left the Aruwimi, and in this case no news is good news, for bad news travels as rapidly in Africa as elsewhere.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

The Royal Society held its Anniversary Meeting yesterday for the purpose of electing officers and presenting medals. The President delivered the address which we print below. After the meeting the Fellows dined together at Willis's Rooms, and the attendance was larger than on any previous occasion, nearly 200 Fellows being present.

During the past year death has removed from us fifteen of our Fellows and one foreign Member. It is remarkable that no less than six of these had reached the age which the Psalmist takes for the extreme duration of human life, while the average age of the whole exceeds seventy-five years. Within two months after our last anniversary Sir Joseph Whitworth died, at the age of eighty-four. Starting from a humble beginning, he attained, through his talent and steady application, a commanding position among constructors of machinery and heavy ordnance, and the truth of surface and accuracy of dimensions of what came from his workshop are probably unrivalled.

Sir Walter Elliot, who was still older, combined a high official position in India with the pursuit of natural history, and was the author of several papers in scientific serials. John Hymers and Thomas Gaskin were mathematicians well known to Cambridge men of some standing, and were both elected Fellows of our Society nearly half a century ago. The former was the author of various mathematical text-books, which for a long time were those chiefly used in their respective subjects by Cambridge students for mathematical honours. The latter, once a colleague of my own in a mathematical honour examination, was famed for his skill in the solution of problems, though he has not left much behind him in the way of mathematical writings, beyond a book containing the solution of a variety of problems. In Robert Hunt we have lost an aged Fellow whose name is well known in connection with the study of the action of light in producing chemical changes, and on vegetation. In Joseph Baxendell we had a man who during a long life was a diligent observer of astronomical and meteorological phenomena. John Arthur Phillips, a geologist who attended most particularly to the chemical origin of mineralogical and geological phenomena, was the author of several papers, some of which appeared in our own Proceedings. It is not long since Sir Julius von Haast was among us, apparently in full vigour, having come to England in connection with the Colonial Exhibition, and now this distinguished geologist and naturalist is no more. The Earl of Iddesleigh was suddenly carried off in the midst of the duties belonging to an important office in the State, whilst Beresford-Hope has succumbed to an illness of some duration. These two joined us under the statute which enables the Council to recommend to the Society for election, in addition to the fifteen who are selected in the ordinary way, and nearly always on account of their scientific claims, persons who are members of Her Majesty's Most Honourable Privy Council, and whose ability is thus attested, though they are not usually men of science. From the list of foreign Members, one name has disappeared which has become a household word among the physicists of all civilized nations. The name of Kirchhoff will ever be remembered as that of the introducer, conjointly with Bunsen, of spectral analysis into the regular work of the chemical laboratory, a step which has been so fertile in results. To him too we owe the reference of the dark lines of the solar spectrum to the absorption of portions of light coming from deeper portions of the sun by the vapours of substances which in the condition of incandescent vapour themselves emit bright lines in corresponding positions; and to him therefore we are indebted for the detection of chemical elements in the sun and stars, though partial anticipations of these discoveries had been made by others. The fertility of these researches, and the attention which they consequently excited, should not make us

forget the many important investigations in mathematical physics of which Kirchhoff was the author.

The present year is memorable as the Jubilee of the reign of Her Most Gracious Majesty our beloved Sovereign, and the Patron of our Society. An address of congratulation on this auspicious event was prepared by the Council, and was graciously received by Her Majesty in Windsor Castle at the hands of your President, who was accompanied on that occasion by the senior Secretary.

It happens that this same year is also the Jubilee of the Electric Telegraph, if we date from the first construction of a telegraph on an actually working scale, as distinguished from preparatory experiments made only in the laboratory. The Jubilee was duly celebrated by the Society of Telegraph Engineers. The name of our former Fellow Wheatstone will go down to posterity as having occupied a foremost place in this great practical application of Oersted's fertile discovery.

I will just briefly allude to another outcome of scientific research. The last half-century was well advanced when our Fellow Dr. Perkin, by utilizing a colour reaction which had been employed by chemists as a test for aniline, laid the foundation of the industry of the coal-tar colours, which has now attained such great proportions, and the investigation of the chemical theory of which has occupied the attention of so many eminent chemists from our own Fellow Dr. Hofmann onwards.

There is yet another Jubilee connected with this same year in which our Society is if possible still more closely connected: it is now just 200 years since the publication of the first edition of that immortal work, "The Principia" of Newton. Some of the important results embodied in the Principia had previously been communicated to the Royal Society.

But, restricting our view to the last half-century alone, we can hardly help casting a glance at the progress of science, and of the practical applications of science, within that period. In electricity, I have already referred to the electric telegraph, now passed into the management of a department of the State, and inwoven in our daily life, with its wires stretching all round the earth like the nerves in the body, and placing us in immediate connection with distant countries. Much more recent than the invention of the electric telegraph is that, in some respects, still more wonderful apparatus for communication at a distance afforded by the telephone. The application of electricity to lighting purposes, of which we have availed ourselves for the lighting of the apartments of our own Society, is an industrial outcome of Faraday's discovery of magneto-electric induction which could not have been thought of when the account of that discovery first appeared in our Transactions. It is true that what I have just been mentioning with respect to electricity consists of industrial applications rather than the discovery of new scientific principles; but these industrial applications react upon abstract science beneficially in more ways than one. The possibility of useful applications induces theorists to engage in investigations which they might not otherwise have thought of, the result of which is oftentimes to lead them to a clearer apprehension of fundamental principles, and to induce them to undertake exact quantitative determinations of fundamental constants. Moreover, the grand scale on which apparatus for actual commercial use has to be constructed renders it possible for scientific men, through the courtesy of those who direct the construction, to make interesting experiments on a scale the cost of which would be quite prohibitory if it were a matter of science pure and simple. Take for example the experiments made by Faraday on the first cable prepared for the attempt to span over the Atlantic Ocean.

When we think of the progress of science, both abstract and applied, during the last half-century, we can hardly help speculating as to the possible increase of scientific knowledge half a century hence. Perhaps we might be tempted to think that the mine must have been so far worked that no great quantity of precious ore can still be left, except what lies too deep for human power to extract. Yet surely the progress of knowledge in the past warns us against any hasty conclusion of the kind. How often have accessions to our knowledge been made which were quite unforeseen and quite unexpected, and how can we say what great discovery may not be made at any moment, and what a flood of light may not result from it?

In what direction such discoveries may be made, it would be rash indeed to attempt to predict. Yet one cannot help thinking of one or two cases in which we seem almost in touch of what if we could reach it would probably give us an insight into the processes of Nature of which we have little idea at present. Take for example the theory of electricity as contrasted with the theory of light. In the latter we have the laws of reflection and refraction, which have long been known, the remarkable phenomenon of interference, the curious appearances which we designate by phenomena of diffraction. But all these fall in the most simple and natural way into their places when we have arrived at the answer to the question, What is light? which is furnished by the statement, Light consists in the undulations of an elastic medium. But we are not at present able to give a similar answer to the question, What is electricity? The appropriate idea has yet to be found. We know a great deal about its laws, and its connection with magnetism and chemical action; we are able to measure accurately physical constants relating to it; we make it subservient to the wants of daily life; and yet we are unable to answer the question what is it? Could we only give a definite answer to this question, it seems likely that the production of electricity by friction, electrostatic attractions and repulsions, the laws of electrodynamics, those of thermodynamics, the nature of magnetism, and magneto-electric phenomena would prove to be all simple deductions from the one fundamental idea. Nay more: so closely is electricity related to chemical action, that could we only clearly apprehend the nature of electricity, it seems not unlikely that an unexpected flood of light might be shed on chemical combination.

Let me refer to one other instance in which a large accession to our present knowledge seems not altogether hopeless. We know that when an electric discharge is passed through a given gas, or between electrodes formed of a given substance, an analysis of the spark reveals a usually complicated spectrum of bright lines characteristic of the chemical substances present. The arrangement of the lines in most cases seems capricious, while in other instances we have repetitions of lines, or else rhythmical flutings, indicative of law, though one of no simple character. There can be no reasonable doubt that the periodic times indicated by the bright lines seen in the spectrum are those belonging to the component vibrations of the chemical molecules themselves; and the appearance is just such as would be produced by a tolerably complex dynamical system vibrating under the action of internal forces of restitution. Now such a system may really be composed of two or more simpler systems, held together less firmly than the parts of one of the simpler systems; and the complex vibrations of the whole may be made up of those of the several simpler systems, modified, however, by their mutual connection, together it may be with others due to the mutual connection of the simpler systems regarded each as a whole. It is conceivable that relations of chemical composition may thus be pointed out even between substances which we deem elementary, and which from their great stability we may, perhaps, never be able actually to decompose.

But I must apologize for having taken up your time with speculations as to the future; I will turn now to some mention of the action of your Council during the past year, and of the progress made by Committees appointed by the Council.

In response to an invitation received from the Academy of Sciences of Paris, that the Society should be represented at the International Conference of Astronomers, which it was proposed should assemble in Paris, in the spring, for the purpose of deliberating about concerted action for obtaining a complete map of the starry heavens by means of photography, your Council requested the Astronomer Royal to represent the Society on that occasion. The Conference met, as it was proposed, last spring; and I believe that the English astronomers at least think that a good foundation has been laid for concerted action in that great undertaking.

As the Fellows are already aware from a circular which has been issued, the Council has decided to make a change in the mode of publication of the Philosophical Transactions. The average yearly volume is a good deal more bulky now than it was at the beginning of the century, and its size is such as not unfrequently to make it desirable to bind one volume in two. The sciences, moreover, which are represented in the Philosophical Transactions, divide themselves very naturally into two groups: mathematics, physics, and chemistry forming one, and the biological sciences the other. The Council has decided to issue the Transactions from henceforth in two series, corresponding to these two divisions, and a yearly volume will appear in each series. It is hoped that this arrangement will be conducive to an earlier publication, as the numeration of the pages in the two series can go on independently. The indi-

vidual papers will also be issued separately, so that Fellows who prefer receiving them in this way can have them as soon as they are printed. Moreover, the issue of the Transactions in two series will enable institutions that are concerned with one only of the two groups of subjects, and that are not on our list for free presentation, to purchase for their libraries the series devoted to that group, instead of going to the expense of procuring the whole Transactions.

I am happy to be able to announce that the publication of the *Challenger* Report is now nearly finished. Twenty-eight volumes, some in two parts, have now been published, and these are all in the Society's library.

The Krakatão Committee have now all but completed their labours. A vast amount of information on the phenomena related to that most remarkable volcanic explosion has been collected and digested, different branches of the inquiry having been taken up by different members of the Committee. An estimate has been made of the cost of publication of the Report, and the Council has decided that it should be published as a separate work, and has voted the sum required for publication. The printing of the volume is now far advanced, and in a very few weeks it will in all probability be in the hands of the public.

The reports of the observers of the total solar eclipse of August last year are now coming in. From inquiries I have made I am in hopes that they will all be in by the end of the year. It is obviously convenient that they should all be dealt with together, rather than appear in a scattered form for the sake of a slightly earlier publication of those which happen to be read first.

I mentioned in my last address that with respect to this eclipse the Council, acting in accordance with the recommendations of the Eclipse Committee, had decided to confine themselves to an expedition to Grenada, without attempting another to Benguela on the Western Coast of Africa, which if sent out from this country would have been a good deal more costly, and of which the success, judging by such accounts of the climate of Benguela and its neighbourhood as we could procure, seemed very doubtful. The Committee guaranteed, however, £100 towards the expense of a small expedition from the Cape in case Her Majesty's Astronomer at that place should be in a condition to organize one. Sir W. J. Hunt-Grubbe, the Admiral in command at that station, was prepared to render every assistance in his power. Ultimately, however, it was not found practicable to organize an expedition from the Cape, and so the English observations of the eclipse were confined to those taken at Grenada. I have heard that the day of the eclipse was fine at Benguela, but there were no astronomers of any nation there to take advantage of it. It may be doubted, however, whether, in spite of the fineness, the haze which is said to prevail so much on that coast at that time of year, might not materially have interfered with the observations.

The boring in the Delta of the Nile has been continued, by the favour of the War Office, under the able and zealous superintendence of Captain Dickinson, R.E. As I mentioned last year, the Committee thought it best to concentrate their efforts on a single boring until rock should be reached, or else a stratum of such a character as to show that the alluvial or drifted deposit had been got through. This result has not at present been obtained. The boring at Zagazig reached the depth of 324 feet, when the tube broke, and stopped for the time further progress. It is, however, a matter of interest and importance to know that the drift or deposit extends to so great a depth. Geologists attach so much importance to the prosecution of the inquiry that at the suggestion of the Delta Committee an application was made to the Government Grant Committee for a grant of £500, which was acceded to by the Committee. This sum would not suffice for the prosecution of the inquiry to the extent contemplated; but it was thought that with such a sum as a nucleus extraneous pecuniary assistance might be obtained from Societies or individuals specially interested in the inquiry, and the Council have authorized the Delta Committee to avail themselves of such aid.

The meetings of Council and Committees continue to be very numerous, and no less than twenty-two Committees and Sub-Committees have been at work during the session.

The number of papers communicated to the Society continues to increase. In 1884-85 the number was 93; in 1885-86 it was 113; and in the past session, 129.

Since the last Anniversary one complete part of the Philosophical Transactions, and thirty-two papers towards the new volume have been published; the whole comprising no less than 1482 pages of letterpress and seventy-six plates. In the same period twelve numbers of the Proceedings, containing 984 pages, have appeared.

The task of preparing the MS. of the Catalogue of Scientific Papers, decade 1874 to 1883, has proved far heavier than was anticipated, and the matter very far exceeds in bulk that of the previous decade. The cataloguing of papers from the volumes in our own library has long been finished, but the work of gleaning stray papers from works in other libraries which we do not possess has proved more arduous than was expected, and even now is not quite completed. It is confidently hoped, however, that the MS. will be completed for the press during the coming session.

The distribution and exchange of duplicates from our library commenced last session has been continued, and several defective series among the periodicals on our shelves have been made good. The general work of the library has received careful attention at the hands of Mr. Alfred White, who shortly before the last Anniversary was appointed to the office of Assistant Librarian.

The Copley Medal for the year has been awarded to the eminent botanist, your former President, Sir Joseph Dalton Hooker. It is impossible, within the limits to which I must confine myself on the present occasion, to do more than briefly refer to some of the more salient features of his scientific career, extending as it does over nearly half a century of unceasing intellectual activity; and I need hardly say that in attempting to give some idea of important labours which lie outside my own studies, I am dependent on the kindness of scientific friends.

As a traveller, he can perhaps only compare with Humboldt in the extent to which he has used travel as an instrument of research. To quote a remark by Prof. Asa Gray, "No botanist of the present century, perhaps of any time, has seen more of the earth's vegetation under natural conditions." His Antarctic voyage in 1839–43 supplied the material for a series of well-known works of first-rate importance on the vegetation of the southern hemisphere; and these in their turn formed the basis of important general discussions. The journey to India in 1847–51 yielded, in the Himalayan journals, as Humboldt has remarked, "a perfect treasure of important observations." The maps made of the passes into Tibet are even still unsuperseded. The fine work on the "Sikkim Rhododendrons" was at once a revelation to the botanist and to the horticulturist. His account of the glacial phenomena of the Himalayas supplied facts both to Darwin and to Lyell. A journey to Morocco in 1871 and a later visit to North America led to important conclusions on plant distribution.

Perhaps Sir Joseph Hooker's most important place in scientific history will be found in the rational basis upon which he placed geographical botany. De Candolle, while admitting the continuity of existing floras with those preceding them in time, still adhered in principle to the multiple origin of species. To quote a remark by Prof. Asa Gray, "De Candolle's great work closed one epoch in the history of the subject, and Hooker's name is the first that appears in the ensuing one." According to Lyell, "the abandonment of the old received doctrine of the 'immutability of species' was accelerated in England by the appearance in 1859 of Dr. Hooker's 'Essay on the Flora of Australia.'" This essay effected a revolution. It was quickly followed in 1860 by the classical essay on the "Distribution of Arctic Plants," and in 1886 by the Nottingham lecture on insular floras. The fact of widely *dissevered* localities for species, which De Candolle found an insuperable obstacle to abandoning the doctrine of multiple origin, has, in the hands of Hooker and A. Gray (as stated by Bentham), afforded the most convincing proof of the genetic relationship of the floras of which such species are components.

In systematic botany, Hooker has perhaps had no rival since Robert Brown. The "Genera Plantarum," the joint work of himself and his friend Bentham, and the "Flora Indica," to the completion of which our colleague is devoting the leisure of a well-earned retirement, form only as it were the head of an immense body of taxonomic memoirs.

Nor have his services to botanical science been confined to geographical botany and to taxonomy. His researches on various groups, such as *Welwitschia* and others, deal in a masterly way with morphological problems of the highest interest and of extreme difficulty.

While no one would attempt to minimize the commanding

and unique position of Mr. Darwin, the scientific historian of the future will recognize how much the development of the modern theory of evolution, from its first conception in the mind of Mr. Darwin, was facilitated by the interaction upon one another of the work and minds of Darwin, Hooker, and Lyell. It was due to the earnest efforts of his two friends that Mr. Darwin was induced to publish the first sketch of the origin of species at all. And no one, had he been alive, would have more cordially recognized than Mr. Darwin how vast an armoury of facts the wide botanical experience of Hooker constantly placed at his disposal in fortifying and supporting his main position.

Of the two Royal Medals, it is customary, though it is not an invariable rule, to award one for mathematics or physics, and the other for biological science.

The medal, which, in accordance with the usual rule, has been devoted to mathematics and physics, has this year been awarded to Colonel A. Clarke for his comparison of standards of length, and determination of the figure of the earth.

Colonel Clarke was for some twenty-five years the scientific and mathematical adviser for the Ordnance Survey, and whilst acting in that capacity he became known to the whole scientific world as possessing a unique knowledge and power in dealing with the complex questions which arise in the science of geodesy.

His laborious comparison of the standards of length, carried out under General Sir Henry James, R.E., are universally regarded as models of scientific precision.

His determination of the ellipticity and dimensions of the earth from the great arcs of meridian and longitude involved a very high mathematical ability and an enormous amount of labour. The conclusion at which he arrived removed an apparent discrepancy between the results of pendulum experiments and those derived from geodesy, and is generally accepted as the best approximation hitherto attained as to the figure of the earth.

The accounts of these investigations have been published in a number of memoirs, several of which have been communicated to the Royal Society.

In 1880 he published a book on geodesy, which, besides giving an accurate account of that science, embodies the main results of the work of his life.

In the biological division of the sciences the Royal Medal has this year been awarded to Prof. Henry N. Moseley for his numerous researches in animal morphology, and especially his investigations on Corals and on Peripatus.

The result of his elaborate investigations on Corals, an account of which has been published in the Philosophical Transactions, was to show that the Milleporidæ and the Stylasteridæ were not, as had been thought, Anthrozoan in nature, but were composite coral-forming hydroids. Many new genera and species were described by him in these memoirs, and in fact a new group of organisms, the Hydrocorallinæ, was not merely indicated, but the complete morphology and systematic subdivisions of that order were worked out.

Moseley's memoir on Peripatus is not less remarkable. He was the first to point out the true nature of this remarkable animal, and to demonstrate that it was in reality an archaic Arthropod. The subsequent investigations of Balfour and Sedgwick have further increased the importance of Moseley's discovery.

Moseley's memoir on the Land Planarians of Ceylon (Phil. Trans., 1872) is an important contribution to the anatomy of the Turbellaria. He was the first to apply the method of section-cutting to the Planarians, and his paper is full of new facts of great importance, which have stood the test of subsequent work over the same ground.

Besides these three great memoirs published in the Philosophical Transactions, Moseley has published numerous minor discoveries, and his spectroscopic observations on the colouring matters of marine organisms have proved the starting-point of valuable investigations.

Mention must not be omitted of Moseley's admirable book, "Notes of a Naturalist on the *Challenger*," which has been justly compared, for the varied ability, interest, and activity which it evinces on the part of the author, to Darwin's "Voyage of the *Beagle*."

Since the date of the works above referred to, Moseley has been chiefly active in the discharge of his duties as Linacre Professor, and the success with which he has directed the work of his pupils is evinced by the important memoirs on zoological subjects which several of them have produced whilst working under his direction. He has himself also published a remarkable discovery with regard to the Chitons. In the shells of many genera and species of these mollusks he has detected highly developed eyes, of which he has described the minute structure.

The Davy Medal for the year 1882 was awarded by the Council to Profs. Mendelejeff and Lothar Meyer conjointly, for their discovery of the periodic relations of the atomic weights. This relation, now known as "the Periodic Law," has attracted great attention on the part of chemists, and has even enabled Prof. Mendelejeff to predict the properties of elements at the time unknown, but since discovered, such as gallium for instance.

But while recognizing the merits of chemists of other nations, we are not to forget our own countrymen; and accordingly the Davy Medal for the present year has been awarded to Mr. John A. R. Newlands, for his discovery of the Periodic Law of the chemical elements. Though, in the somewhat less complete form in which the law was enunciated by him, it did not at the time attract the attention of chemists, still, in so far as the work of the foreign chemists above mentioned was anticipated, the priority belongs to Mr. Newlands.

SCIENTIFIC SERIALS.

Rivista Scientifico-Industriale, October.—On the crepuscular phenomena of 1883–84, by Prof. Annibale Riccò. These remarks are made in connection with the author's comprehensive work, now nearly ready for the press, on the remarkable after-glows of the years 1883–84. One of the chief conclusions arrived at in this work, after a careful consideration of all the evidence, is that the volcanic theory, first advanced by Mr. Norman Lockyer, is the only one that can be now accepted. The light-effects appeared soon after the great eruption of Krakatão on August 27, 1883, were propagated from the neighbourhood of the volcano to the most distant parts, and then gradually died out, precisely in the same way that similar manifestations were made immediately after the eruption of the island of Ferdinandea (Julia) in 1831. It is further concluded that the after-glows were due, not to the ashes or scoriæ ejected by Krakatão, but to the condensation of the aqueous vapours caused by the volcano, which condensation increased the quantity of solar light reflected by the atmosphere.

Bulletin de l'Académie Royale de Belgique, October.—On the mass of the planet Saturn, by L. de Ball. By a comparative study of its satellites, made at the Observatory of Cointe during the winter of 1885–86, the author finds the mass of Saturn to be 1/3492·8 that of the sun, which is rather less than the values obtained by Meyer, Hall, and Struve, which are 1/3482·5, 1/3481·3 and 1/3490·8 respectively.—Experimental researches on the sense of vision in the Arthropods, by Felix Plateau. Of this elaborate memoir the first part only appears in this issue, dealing first with the work already accomplished down to the year 1887 on the structure and functions of simple eyes; secondly, with the eyes of Myriapods. The four remaining parts, to be published in subsequent numbers of the *Bulletin*, will treat of vision in the spiders, and in larvæ generally; of the part played by the frontal eyes in perfect insects; of compound eyes and the perception of movements; with an anatomico-physiological summary, and experiments with insects.—Remarks on the total solar eclipse of August 19, 1887, by L. Niesten. A comparative study of the photographs obtained by MM. Niesten and Karelin at the station of Jurjewetz, shows that with Van Monckhoven's sensitive plates an almost instantaneous image is obtained not only of the protuberances but also of the corona; and further that a pose of thirty seconds gives no more detailed images of the corona than those obtained at the end of eight seconds. Hence it would appear that photographs of the corona obtained after an exposure of over a minute should be attributed to physical phenomena due to the atmospheric conditions, or to light-effects produced in the photographic apparatus itself.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, November 3.—W. Carruthers, F.R.S., President, in the chair.—Mr. J. H. Hart, of Trinidad, was elected a Fellow of the Society.—The President called attention

to the death-roll since last June meeting, specially deploring the loss of Prof. Julius von Haast, N.Z., Dr. Spencer Baird, U.S., and Prof. Caspary, of Königsberg.—Mr. H. N. Ridley gave an account of his natural history collection in Fernando Noronha. The group of islands in question is in the South Atlantic, 194 miles east of Cape San Roque. The largest is about five miles long and two miles across at broadest part. Although chiefly basaltic, phonolite rocks crop up here and there. The indigenous fauna and flora seem to have been much modified, and in some cases extirpated, by human agency. Of mammals, the cat is reported to have become feral, and rats and mice swarm; Cetacea occasionally frequent the coast. The land-birds comprise a dove, a tyrant, and a greenlet (*Virio*). Sea-birds are numerous, though apparently less so than in the time of the early voyagers. Among reptiles occurs an Amphisbæna, a Skink, and a Gecko; turtles also haunt the bays. The absence of batrachians and fresh-water fish is noteworthy. A well-known Brazilian species of butterfly is plentiful. Though insects generally are abundant, there are, notwithstanding, but few species. Two shells (*Trochus*) show a southern distribution, though other marine forms indicate West Indian relationship. Several interesting plants were got, a *Solanum* with medicinal properties, a new *Erythrinm*, and flower of the "Burra," a Euphorbiaceous tree. Of ferns, mosses and hepatics, lichens and fungi, several interesting sorts were collected.—Mr. Geo. Murray exhibited *Vallonia ovalis* from Bermuda and Grenada; the former sort consisting of a balloon-shaped cell an inch long and two wide. He explained by diagrams the development of *V. utricularis*, incidentally comparing this with *Sciadium*.—Prof. Marshall Ward showed specimens and made remarks on the peculiar development of *Agaricus* (*Amillaria*) *melleus*.—Mr. E. A. Heath exhibited examples of fruits of two species of *Solanum* from Barbados.—A paper was read on the scars occurring on the stem of *Dammara robusta*, by Mr. S. G. Shattock. He says that the process of disarticulation of the branches is like that by which a leaf or other organ is shed. The parenchymatous cells across the whole zone of articulation multiply by transverse division, a layer of cork resulting from the formation of this secondary meristem, and through the distal limits of this, solution of continuity occurs. After this the slender connecting bond of wood is broken across by the weight of the branch or the first trivial violence; this completion of the process being aided, perhaps, by the tension made upon the wood in consequence of the cell-division of the surrounding parenchyma which occurs across its axis. It thus happens that the whole of the parenchymatous system of the stem is closed by cork *before* the branch is actually shed.—A communication followed, by Messrs. J. G. Baker and C. B. Clarke, on the Ferns of Northern India; it being a supplement to a memoir published in the Society's Transactions.

Physical Society, November 12.—Prof. W. E. Ayrton, F.R.S., Vice-President, in the chair.—Lieut. Bacon, R.N., was elected a member of the Society.—Owing to the illness of Dr. Shettle, the paper announced to be read by him was postponed. —The following communication was read:—On a geometrical method of determining the conditions of maximum efficiency in the transmission of power by alternating currents, by Mr. T. H. Blakesley. In this paper the author confines himself to the consideration of a simple circuit containing generating, conveying, and recipient parts, in which the E.M.F. follows the law of sines. The maximum E.M.F.'s of both machines are supposed known, together with the resistance and coefficient of self-induction of the complete circuit. The variable on which the efficiency of transmission depends is the difference of phase of generator and receiver. A geometrical construction is given by which the phase which gives maximum efficiency can be determined. Mr. Kapp thought the construction would not apply where the receiver does mechanical work, owing to the E.M.F. not being a true sine function of the time. He also mentioned an experiment performed on a motor driven successively by alternating and direct currents, in which the *apparent* power $\left(\sqrt{\bar{e}^2}\sqrt{\bar{c}^2}\right)$ supplied by alternating currents was about five times that required when direct currents were used, the motor giving out the same power in the two cases. From this he inferred that the ratio of power to weight is much greater for a direct than for an alternating current motor. This he considered a serious drawback to the use of alternate currents for transmitting power. After some remarks by Prof. Ayrton and Prof. S. P. Thompson, Mr. Blakesley said that by placing a condenser between the terminals of the recipient machine a greater current could be passed through the receiver than that in the generator and line.—Prof. A. W. Rücker exhibited and described a lecture experiment for determining the velocity of sound. The principle of the arrangement is that used by Fizeau in determining the velocity of light. A vibrating reed is used as the source of sound and a sensitive flame as receiver. A long U-shaped tube has its two ends placed near and parallel to the plane of a perforated disk, which is capable of rotating about an axis perpendicular to its own plane. The reed and sensitive flame occupy similar positions on the opposite side of the disk. On rotating the disk, the sensitive flame flares or is quiescent according as the time taken to travel the length of the tube is an even or an odd multiple of $\frac{T}{2n}$, where T is the time of one revolution and n the number of holes in the disk.—Mr. Bosanquet exhibited a form of polariscope he had made some time ago for researches on the polarization of the sky. Its chief feature is a compound prism of right- and left-handed quartz which shows coloured bands with polarized light, whatever be the direction of the plane of polarization. It also forms a very sensitive object for polarimeters.

Zoological Society, November 15.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the months of June, July, August, September, and October, 1887, and called attention to certain interesting accessions which had been received during that period.—A communication was read from Herr W. von Nathusius, of Königsborn, on *Symbiotes equi*, a parasite of the horse, causing what is called "greesy-foot," of which he sent specimens for exhibition.—The Secretary read a letter addressed to him by Dr. Emin Pacha, dated Wadelai, April 15, 1887, referring to some communications which he was proposing to offer to the Society. —A letter was read from Surgeon-General George Bidie, referring to a case of the breeding of the Elephant in captivity.—Prof. Bell made some observations on the "British Marine Area," as proposed to be defined by the Committee of the British Association. Prof. Bell opposed the idea of omitting the Channel Islands from the British area.—Prof. A. Newton, F.R.S., exhibited (on behalf of Mr. W. Eagle Clarke) a specimen of Bulwer's Petrel (*Bulweria columbina*), believed to have been picked up dead in Yorkshire.—Mr. H. E. Dresser exhibited (on behalf of Lord Lilford) specimens of a new species of Titmouse allied to the Marsh-Tit (*Parus ater*), obtained by Dr. Guillemard in Cyprus, which he proposed to designate *Parus cypriotes*.—Mr. Boulenger exhibited a living specimen of a rare African Batrachian (*Xenopus lævis*), which had been sent to him by Mr. Leslie, of Port Elizabeth.—Prof. Flower exhibited a photograph of a specimen of Rudolphi's Whale (*Balænoptra borealis*), taken in October last, in the Thames near Tilbury.—Mr. G. A. Boulenger, read an account of the Reptiles and Batrachians collected by Mr. H. H. Johnston on the Rio del Rey, West Africa. Amongst these were examples of two species of Batrachians new to science. —Mr. Edgar A. Smith read some notes on three species of shells obtained by Mr. H. H. Johnston at the Rio del Rey, Cameroons. —Mr. A. G. Butler read a paper containing an account of two small collections of African Lepidoptera obtained by Mr. H. H. Johnston at the Cameroons and the Rio del Rey.—A communication was read from Mr. G. E. Dobson, F.R.S., on the genus *Myosorex*. The paper contained the description of a new species from the Rio del Rey (Cameroons) district, which he proposed to call *Myosorex johnstoni*, after Mr. H. H. Johnston, who had sent home the specimens.—Mr. G. A. Boulenger gave the description of a new species of *Hyla* from Port Hamilton, Corea, living in the Society's Gardens, which he proposed to name *Hyla stepheni*, after its discoverer.

Institution of Civil Engineers, November 8.—Mr. G. B. Bruce, the new President, after presenting the medals and premiums announced at the annual meeting in May last, delivered his address on assuming the chair for the first time. Having entered upon his apprenticeship in the locomotive works of Robert Stephenson within a few months of the beginning of the present reign, the President chose the state of engineering then and in the Queen's Jubilee year as the subject of his remarks. Starting with the workshop, in 1837 machine-tools were practically unknown, reliance being placed upon the skill of the workmen, who could chip and file by hand almost as truly as the machine. It was scarcely credible, but it was a fact, that there

was not a single crane in Robert Stephenson's shops in 1837; and the only steam-engine, in that which was the most important locomotive shop in the world of that day, was a vibrating pillar-engine, with a single 16-inch cylinder and 3-feet stroke. About the only machine-tool, properly so called, in the works was a planing-machine, which probably weighed about 3 tons. At the present time there were lathes 75 feet long, weighing 100 tons, giving a yield of steel-turnings at the rate of 10 and 20 tons a day, and planing-machines weighing 90 tons and operating over surfaces of 20 feet by 15 feet. Having spoken of the changes in the position of the workmen, the President referred to the progress of railways, the development of the iron and steel industries, and sanitary engineering. Reference was made to the electric telegraph, which had developed from the 5-needle instrument of Cooke and Wheatstone, employing six wires and working at about the rate of four words a minute, to the system of multiplex and automatic telegraphy, by means of which six messages could be sent at once on one wire with a speed of, say, 600 words per minute. Touching successively on the telephone, electric light, and the application of electricity as a motive power, the President hazarded the opinion that when some way should have been discovered of storing up in a more efficient and financially successful manner the unemployed forces of Nature, such as the winds and tides, then would electricity become a factor in the world's life compared with which it was at present as nothing.

Anthropological Institute, November 22.—Prof. Flower, C.B., Vice-President, in the chair.—Canon Isaac Taylor read a paper on "The Primitive Seat of the Aryans," in which he urged the view that the Finns are the nearest representatives of the ancient Aryan stock, and that the race took its origin in North Germany.

Edinburgh.

Royal Physical Society, November 16.—Prof. Duns delivered the introductory address for the session 1887–88. At the outset obituary notices of several deceased Fellows were given, notably of Mr. Robert Gray, the late Secretary of the Society. After some remarks upon the history and progress of the Society, he passed on to consider the claims of Scotland upon Government aid for scientific purposes, and advocated the union of the various scientific corporations of Edinburgh to form an Academy of Science for dealing with general questions of this nature.

Paris.

Academy of Sciences, November 21.—M. Janssen in the chair.—On the nervous system of the Gasteropods (Aplysia type, *A. depilans* and *A. fasciata*), by M. H. de Lacaze-Duthiers. The Aplysia, a large mollusk, abounding especially in the Mediterranean seaports, is here studied for the purpose of determining the type of its nervous system in order to compare it with those of Gadinia, Testacella, and other Gasteropods already described by the author.—Remarks in connection with M. Colladon's recent note on waterspouts and tornadoes, by M. H. Faye. It is again shown that M. Colladon's illustration, as published in the *Comptes rendus*, has only a very remote connection with true waterspouts and whirlwinds. Reference is also made to the statement, in W. Ferrel's new work on meteorology, that much sea-water is carried up by the ascending current of waterspouts, the fish and other animals in small ponds being even in this way borne aloft and wafted to great distances. On the contrary, M. Faye insists with Lieutenant Finley, of the United States Signal Service, that no appreciable quantity of water is pumped up in this way, although much is driven horizontally to the right and left by the gyratory velocity of the air, which has always a descending, and never an ascending motion.—On the crystalline form of cinchonamine, by M. C. Friedel. Some crystals of the alkaloid discovered by Arnaud in certain varieties of quinquinas are described as hexagonal prisms terminating in a rhombohedron and of the true orthorhombic type.—On a meteorite which fell on August 18/30, 1887, at Taborg, in the Government of Perm, Russia, by M. Daubrée. This meteorite, which has but slight cohesion, with density 3·620, appears to closely resemble those which fell on April 1, 1857, at Heredia (Costa Rica); on May 14, 1861, at Canellas, Province of Barcelona (Spain); on January 19, 1867, at Khethree, Rajputana (India); and on August 17, 1875, at Feid Shair (Algeria).—On a simple relation between the wave-lengths of spectra, by M. A. E. Nordenskjöld. The researches here described tend to confirm the author's previous view that, at least in the spectra of certain simple bodies, the differences between the logarithms of the wave-lengths of each element are simple multiples of the same number. The universality of this law, as applicable to the spectra of all bodies, is still far from being established. But further investigation will probably show, either that the spectra of all simple bodies conform absolutely to this law, or else that they are disposed in more or less independent groups, to which the law may still be applicable.—On the volcanoes of Hawaii, by Mr. James Dana. Reserving for the *American Journal of Science* a detailed account of a recent visit to these volcanoes, the author here remarks chiefly on the remarkable fluidity of the lavas, and on the fact that the eruptions show no sign of being in any way associated with the surrounding marine waters. The salts deposited in the hottest recesses, and those of solfataras, do not appear to have hitherto yielded any chloride, while the sulphate of soda is very common.—Researches on meteorites: general conclusions, by Mr. J. Norman Lockyer.—Observations of Olbers' comet (1815 I.), at its return in 1887, made with the 0.38 m. equatorial of the Bordeaux Observatory, by MM. G. Rayet and F. Courty. The observations cover the period from September 8 to September 25.—On sidereal evolution, by M. Stanislas Meunier.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Die Welt in Ihren Spiegelungen unter dem Wandel des Völkergedankens. Prolegomena zu Einer Gedankenstatistik; Ethnologisches Bilderbuch mit Erklärendem Text: A. Bastian (Mittler, Berlin).—Sound, Light, and Heat: M. R. Wright (Longmans).—A Primary Geometry: S. E. Warren (Trübner).—Quantitative Chemical Analysis: Classen and Herrick (Trübner).—Myth, Ritual, and Religion: A. Lang (Longmans).—Translations of Foreign Biological Memoirs, I. Memoirs on the Physiology of Nerve, of Muscle, and of the Electrical Organ, edited by J. Burdon-Sanderson (Clarendon Press).—Earth Knowledge: Harrison and Wakefield (Blackie).—Colour: Prof. A. H. Church (Cassell).—Elementary Microscopical Manipulation: T. C. White (Roper and Drowley).—Quarterly Journal of Microscopical Science, November (Churchill).—Annales de la Faculté des Sciences de Toulouse, tome i., 1887, 4 parts (Gauthier-Villars, Paris).

TECHNICAL EDUCATION IN MANCHESTER.

PROFESSOR HUXLEY could scarcely have anticipated the ready response Manchester has given to the challenge he threw down at the close of his most able address at the Town Hall on the 29th ult. In speaking of one of the great problems of the day, that of meeting ever-increasing competition and yet maintaining the proper social condition of the workers, he said:—"I have ventured to put this before you in a bare and almost cynical fashion because it will justify the strong appeal which I make to all concerned in this work of promoting industrial education to have a care at the same time that the conditions of industrial life remain those in which the physical energies of the population may be maintained at a proper level, in which their moral state may be cared for, in which there may be some days of hope and pleasure in their lives, and in which the sole prospect of a life of labour may not be an old age of penury. . . . I therefore confidently appeal to you to let those impulses have full sway, and not to rest until you have done something better and greater than has yet been done in this country in the direction in which we are now going."

Only a few hours before the utterance of these words the trustees of the late Sir Joseph Whitworth—who during his life-time did so much to encourage and promote the higher education of working engineers—made a munificent offer to the city of Manchester; an offer which was only made public by Mr. Darbishire after Prof. Huxley had finished his address, and which goes some way towards realizing what Prof. Huxley remarks may by some be looked upon as the Utopian dream of a student. The gift consists of a plot of land of about twenty-five acres in one of the best situations in the city, which the trustees have purchased for the sum of £47,000. They propose to offer the whole of this to the Corporation of Manchester upon trust, two-thirds to be maintained as a public park, and one-third as a site for the following institutions: (1) an appropriate Institute of Art, with galleries for paintings, for sculpture and moulded form, and for architectural illustration; (2) a comprehensive Museum of Commercial Materials and Products; (3) a Technical School on a complete scientific and practical scale. The necessary buildings are to be raised by the Corporation and by public-spirited inhabitants of the great district which owns Manchester as its metropolis; and the Whitworth Trustees add that, if this work be heartily undertaken, their own further contributions may be looked for.

Such a result of the movement for the Extension of Technical Education and for the higher culture of our toiling thousands may indeed be welcomed, and the National Association, under whose auspices this meeting was held, may well be congratulated on this outcome of its autumn work. But this is not all, for it is not unlikely that the surplus, amounting, it is believed, to about £50,000, now placed at the disposal of the guarantors of the Jubilee Exhibition, may be applied to furthering this enterprise. Manchester has thus before it the prospect of showing England what can be done to promote educational progress in this direction, and to inaugurate a movement which ought to be followed by all the great cities in the country. Can we doubt that the sons of those whose energy and clear-sightedness have in times past placed Manchester in the van of the most important social movements of the day will prove themselves equal to the task which they have now a splendid opportunity of accomplishing? It is by caring thus for the well-being of our workers that the stable condition of society, referred to by Prof. Huxley, can be best secured; for truer words were never spoken than those in which he stated his belief that, in order to succeed in the competition which is every day becoming more keen, it is not sufficient that our people shall have the knowledge and the skill which are required, but that they must also have the will and energy and the honesty without which neither knowledge nor skill can be of any permanent avail. Mere technical instruction in handicraft or science must, in short, be based on a sound preliminary education. We need to train our workers to be not only clever artisans, but honest men who take pride in the quality no less than in the quantity of their work. It is because these were the views upheld by Sir Joseph Whitworth, and acted upon by him during his lifetime, that his trustees have felt that in no better way could they carry out the important ends for which he laboured than by starting a movement having for its object not merely the technical training of the artisan, but his moral, intellectual, and physical advancement. H. E. R.

TRIDIMENSIONAL FORMULÆ IN ORGANIC CHEMISTRY.

Dix Années dans l'Histoire d'une Théorie. Deuxième Édition de "La Chimie dans L'Espace." Par J. H. Van 't Hoff. (Rotterdam: P. M. Bazendijk, 1887.)

THIS interesting monograph gives an account, partly historical, partly expository, of what in our opinion is the most important theoretical contribution towards solving the problem of the constitution of organic compounds that has been made since the idea of a definite union of atoms within the molecule was first introduced into chemistry, of which idea, indeed, the new theory is an expansion. The work has the advantage of being written by one of the originators of the theory.

The linked-atom formulæ, which have so powerfully aided the development of organic chemistry, never professed to give any information as to the relative positions of the atoms in space. All that the "links" or "bonds" denoted was the existence of a closer relation of attraction (of a kind not further specified) between atoms represented as directly linked than between atoms represented as not directly linked. The question of the actual position of these atoms was left entirely open. If, therefore, anyone gathered from the graphic formula of methane,

```
   H
   |
H—C—H,
   |
   H
```

for example, that the five atoms of this compound were necessarily situated in one plane, that person was merely

permitting the geometrical properties of paper (or black-boards) to influence his conceptions unduly.

In the great majority of cases the ordinary graphic formulæ fulfilled the purpose for which they were primarily devised: they enabled chemists to predict the number and constitution of the isomerides possible for any given combination of atoms. But there were cases, on the other hand, in which the number of isomerides discovered by experiment exceeded that predicted by the theory. This was especially noticeable in the case of those compounds which in the liquid form or in solution produce rotation of the plane of polarized light. Thus, of three compounds to which chemists, from a study of their modes of formation and decomposition, were obliged to ascribe identical atomic linkage, one would be found to cause rotation of the polarized ray to the right, another to the left, whilst a third was optically inactive. As this optical difference was frequently the only difference discoverable, the phenomenon was described as "physical" isomerism—a name which appeared to suggest that the investigation of it lay outside the province of chemistry. Wislicenus, however, in 1873, in discussing an isomerism of the foregoing type occurring in the case of fermentation-lactic acid and paralactic acid, suggested that this was really a "geometrical" isomerism; that, although the mode of linkage of the atoms was undoubtedly the same in the two compounds, the positions of the atoms in space were different.

The demand thus made for a system of tridimensional formulæ was speedily responded to. In the following year, Van 't Hoff, in Holland, and Le Bel, in France, independently, and almost simultaneously,[1] suggested a very simple hypothesis with regard to the distribution of the four affinities of the atom of carbon. From this hypothesis they developed a system of formulæ under which not only the old anomalies of isomerism disappeared, but new lines of experiment in the preparation of unknown isomerides were indicated.

Van 't Hoff and Le Bel called attention to the hitherto unnoticed fact that all organic compounds which in the liquid state or in solution exhibit optical activity, contain in their constitutional formulæ at least one carbon atom, the four affinities of which are satisfied by four *different* atoms or groups. Such a carbon atom they termed, for reasons to be explained presently, "asymmetric" (Van 't Hoff), or "dissymmetric" (Le Bel).

With regard to the distribution of the affinities of an atom of carbon, Van 't Hoff and Le Bel made the assumption that the four monad atoms or groups satisfying the four affinities of such a tetrad atom are situated at the solid angles of a tetrahedron, the centre of which is occupied by the carbon atom. If, now, the four monad atoms or groups are dissimilar, as in the case of optically active compounds, it is possible to arrange them about the angles of the tetrahedron in two different ways, so as to produce two *asymmetric* tetrahedra (considered with regard to the positions of these atoms or groups)—two non-superposable tetrahedra, one of which is the mirror-image of the other. A continuous curve, passing through the four atoms or groups in the same order, will in the one case describe a right-handed, in the other a left-handed, screw-line. Two compounds thus differing in atomic structure only as regards conditions of symmetry might be expected to possess the same chemical and physical properties, save where dissymmetry or polarity is concerned. As a fact, this is found to be the case with optically active compounds. When a compound contains an asymmetric carbon atom, this compound, provided that it has been adequately investigated, can always be shown to exist in two modifications, possessing the same chemical properties and displaying the same chemical reactions, and, as regards physical properties, agreeing in melting-point, boiling-point, solubility, specific gravity, and all other properties not involving the operation of polar forces. But let dissymmetry or polarity in any form intervene, and the non-identity of the two compounds is at once manifested. Thus, as regards the action of the compounds upon polarized light, the one compound turns the polarized ray through a given angle to the right, the other through the same angle to the left. Again, if the two compounds crystallize, although they do so in forms belonging to the same system and having the same angles, yet the crystals exhibit hemihedral faces which are situated to the right in the one case, and in the other to the left. The one crystal is thus the mirror-image of the other—a relation corresponding with that which is supposed to prevail between the asymmetric carbon atoms themselves within the molecule. These two hemihedral crystals also display opposite pyro-electricity. Even the otherwise identical chemical action of the two compounds may be modified by the dissymmetry of a third compound with which they combine; thus, for example, a dextro-rotatory and a lævo-rotatory acid differ in the degree of their affinity for a dextro-rotatory base, and the two resulting salts are generally quite distinct in their properties.

In all artificial syntheses of compounds containing an asymmetric carbon atom the substance obtained is optically inactive. This was to be expected. The chances in favour of the formation of each of the two modifications of opposite rotatory power are equal: both are therefore formed in equal quantity; and the resulting mixture is inactive. There are three known methods of separating the optically active constituents of such a mixture. These methods, due to M. Pasteur, were discovered, it should be mentioned, many years ago, before the Van 't Hoff-Le Bel hypothesis was put forward. The separation is effected: (1) by the greater ease with which one of the two modifications is attacked by some particular micro-organism, it being thus possible to destroy the whole of one modification leaving the other almost intact, and by properly selecting the organism even to destroy at will either the dextro-rotatory or the lævo-rotatory modification; (2) by the different degree of affinity which the two modifications exhibit towards some other optically active compound; and (3) by means of the factthat under certain conditions of temperature and concentration it is sometimes possible to separate the two modifications by ordinary crystallization. By these means Pasteur succeeded in breaking up racemic acid into dextro-tartaric and lævo-tartaric acids.

[1] Van 't Hoff's views were first published in a pamphlet in the Dutch language, in September 1874. Le Bel's original memoir appeared in the *Bulletin de la Société Chimique*, in November of the same year. In May 1875, Van 't Hoff published his pamphlet, "La Chimie dans l'Espace." which, however, did not attract much notice until the appearance of the German translation by Herrmann in 1877.

Optical inactivity may also be due to mutual compensation between two asymmetric carbon atoms, of equal and opposite asymmetry, within the molecule itself. This is the case with inactive tartaric acid.

At the present moment there is no case known which contradicts the foregoing hypothesis. A few substances, which, at the time when the hypothesis was first put forward, were believed to be optically active, and yet contained in their molecule no asymmetric carbon atom, have since been shown to owe their supposed optical activity to impurities. On the other hand, the presence of an asymmetric carbon atom in the formula of an apparently inactive compound has been an indication to chemists that the resolution of the compound into two isomerides of opposite optical activity might be profitably attempted; and in the long list of such attempts that have been made within the last few years there appears to be no record of failure.

We have already alluded to M. Pasteur's classical researches on the tartaric acids, in which he not only rendered the Van 't Hoff-Le Bel hypothesis possible by elucidating all the various modes of optical activity and inactivity which it contemplates, but also devised the methods which have so facilitated its experimental development. It only remains to show how near this great investigator came to anticipating the entire hypothesis. In a passage written in 1860, quoted by Prof. Van 't Hoff, M. Pasteur says, referring to the tartaric acids:—

"Les atomes de l'acide droit sont-ils groupés suivant les spires d'un hélice dextrorsum, ou *placés aux sommets d'un tétraèdre irrégulier*, ou disposés suivant tel ou tel assemblage dissymétrique déterminé? Nous ne saurions répondre à ces questions. Mais ce qui ne peut être l'objet d'un doute, c'est qu'il y a groupement des atomes suivant un ordre dissymétrique à l'image non-superposable. Ce qui n'est pas moins certain, c'est que les atomes de l'acide gauche réalisent précisément le groupement dissymétrique inverse de celui-ci."

This is divination indeed!]

We must content ourselves with merely referring to another portion of the subject—the application of the carbon tetrahedron to the explanation of anomalous cases of isomerism occurring among unsaturated compounds; of which *allo-isomerism*, as Prof. Michael has termed it, fumaric and maleic acids may be taken as illustrations. This application, first made by Van 't Hoff in 1874, and accepted later by Le Bel, has undergone within the past year an extension of extraordinary importance at the hands of Prof. Wislicenus in his elaborate memoir "Ueber die räumliche Anordnung der Atome in organischen Molekulen und ihre Bestimmung in geometrisch-isomeren ungesättigten Verbindungen" (*Abhandl. der Königl. Sächs. Gesellsch.*, 1887), of which a very full and appreciative summary is given by Prof. Van 't Hoff in the present work.

The tridimensional formulæ of organic chemistry are thus an accomplished fact. The treatment of the subject is still, of course, only statical; but, taking care not to lose sight of the limitations thus imposed, the method is a perfectly legitimate one.

F. R. JAPP.

THE MAMMOTH AND THE FLOOD.

The Mammoth and the Flood: an Attempt to Confront the Theory of Uniformity with the Facts of Recent Geology. By Henry H. Howorth, M.P., F.S.A. (London: Sampson Low and Co., 1887.)

MR. HOWORTH'S book is not disproportionate to its subject. But even as the mammoth it had a small beginning. It saw light as letters in NATURE. It cast its swaddling-clothes at the British Association. Grown larger, it took passage on board the *Geological Magazine*, and, as some thought, threatened to swamp that useful but far from bulky periodical. Now, with body and tusks alike full-grown, it comes forth to champion cataclysm and scatter the uniformitarians.

The book consists partly of facts, partly of theories. The one part is separable from the other, though of course sometimes the facts are regarded in the light of the theories. We will endeavour in our notice to keep them apart. The first chapter of the work a little reminds us of the *hors d'œuvre* which sometimes precedes a banquet. Appetizing bits, dainty but miscellaneous—the etymology of mammoth, and its identity with behemoth; griffons and their claws; fossil unicorns; dragons' bones; Indian fabulous beasts; stories of giants, and their bones: with such subjects is the reader's palate stimulated. The next chapter gives a history of opinion on the subject of the remains of the mammoth and the woolly rhinoceros. The author then discusses the abode and range of the mammoth in Asia. He considers it to have been limited to the tundras, which must at that time have enjoyed a climate far more temperate than at the present. Then comes an account of the various discoveries of carcasses, either of the mammoth or of the woolly rhinoceros, in Siberia; followed by the history of the same animals and their associates in Europe. The climate of Europe, when frequented by them, is next discussed, and the facts bearing on the extinction of the mammoth are enumerated, particular stress being laid on the evidence of caves and fissures. Palæolithic man is next called into the witness-box, and cross-questioned as to the cause of his disappearance. That he was exterminated by Neolithic invaders does not, to the author, seem a satisfactory theory. That he was a victim of the Deluge is a simple explanation. The Old World is now quitted for the New—the two Americas are examined. In each, at no distant time, huge mammals flourished; their remains are found under circumstances not materially different from those of similar quadrupeds in the Old World. So they also must have perished in like manner: the Deluge was not limited to Siberia nor to the Old World; it swept alike over tundra and morass, over prairie and pampa; it inundated the New. Of course the West Indies could not escape; apparently no corner of the earth eluded the devastating waves, for Australia, Tasmania, and New Zealand tell the like tale of extinguished life, and sudden devastation. Lastly, there is the citation of historical evidence, in the form of brief summaries of the many variations of the widespread tradition of a universal deluge.

The facts, as indicated by the above statement—which is only a concise summary of the table of contents—cannot wholly be disentangled from the theories, in the light of which they are viewed and in proof of which

they are ranged. Still, their value is independent of the theories: for the author has dealt with them in the spirit of an advocate, but of an honest advocate. If, indeed, Mr. Howorth can be accused of any forensic art, it is in this very pardonable respect—that the most is made of the opinions of geologists who have held views generally favourable to his own. Thus the unwary and but slightly scientific reader almost trembles before such a weight of authority, and is afraid to question an opinion favoured by so many lights of the heroic age of geology. But in citing authorities it must always be remembered that, unless it can be shown that all the important facts on which an induction is now founded were before them also, the value of their opinion is greatly affected, and it may even be comparatively small. Further, if satisfied on this point, we must inquire whether any, and, if so, what, alternative hypotheses had been presented to them. These preliminary considerations are often overlooked in quoting authorities, yet their importance cannot be disputed. The mind is greatly influenced by early impressions and by the hypotheses which it has accepted. In the multitude of facts we to some extent find what we seek, miss those of whose value we are ignorant, and without any conscious unfairness select those things which support the accepted view. Anyone who has had in the course of his life to reconsider and to modify an induction formerly maintained must be conscious that in this respect he has innocently erred. Probably, only a cantankerous-minded investigator wholly escapes this infirmity, and for him other snares are laid. Hence in this matter the testimony of even such men as Buckland, or Cuvier, or D'Archiac, is of small value, because not only has a vast store of new facts been acquired since their time, which have influenced or modified almost every branch of geology, but also because the widespread belief in a universal deluge and the virulent attacks made on geology by well-meaning but unthinking theologians had produced a natural readiness to welcome everything which seemed to harmonize with the Biblical narrative.

Mr. Howorth urges that a catastrophic occurrence is not excluded by a rational view of uniformitarianism—which position, we imagine, few would dispute in the abstract; but issue would often be joined as to which explanation were the more probable. He points out also that it is quite possible for a particular form of a tradition to be unhistorical, and yet for the tradition itself to have a true foundation, a remark which is certainly just, and which is sometimes forgotten. But, admitting these axioms, the asserted occurrence of any particular cataclysm is a question of evidence; and it is not enough for Mr. Howorth to show that his hypothesis explains some difficulties which exist in the other, unless he further prove that it is not only in accordance with a larger number of facts, but also does not create a new class of difficulties still more formidable.

Mr. Howorth's preface sounds no uncertain note, as the following extract will show:—

"The coral-insect (*sic*) raises the islands of the Pacific, and the fall of leaves in a tropical forest piles up deep black soil. These cases are no doubt cases of continuous change; but if we turn elsewhere we have to explain a very different state of things. The great gaping cliffs and sheer precipices of the Alps, the splintered pyramids of the Sierra Nevada, the cañons of Colorado, the huge dislocations of the strata, involving faults of hundreds of fathoms in extent, so near us as Durham. These have not the look of gradual changes."

We rub our eyes, and wonder whether the last fifty years have been all a dream. Here are dead and gone geological ideas in full vigour. We had thought that if there was one spot on earth in which catastrophe could not be invoked, where the uniformitarian could be in peace, it was the Colorado cañons; and we cannot help thinking that if Mr. Howorth were a member of the English Alpine Club he would by this time have convinced himself that, whatever signs of ruin the Alps may afford, there are none of any vast catastrophe. It is therefore evident that Mr. Howorth's method of interpretation differs from that of geologists in general, and this must throughout the book be borne in mind by the reader. But Mr. Howorth is always rather a special pleader, ingenious sometimes, but generally inconclusive. Granting that occasionally he contrives to give a smart rap to the irrational uniformitarian (for such a person does exist) and hits upon a defect in an hypothesis, he straightway goes on to propose a solution involving greater difficulties. In a brief notice it is impossible to deal with particular instances, but some general indications may be given The carcasses of mammoths are found embedded in ice in the north of Siberia. It is admitted that, from their state of preservation, they must have been frozen up very shortly after death, and have so remained ever since. There are no doubt considerable difficulties in attributing their transport to a river flood, as Mr. Howorth points out; nevertheless, when we remember the peculiarities of the Siberian rivers, and that in a cold region a carcass would be slow to decompose, for the flesh might freeze before it ceased to drift, these do not seem insuperable. Mr. Howorth, as an alternative, offers the hypothesis of a deluge, followed by a sudden change of temperature, but, apart from the difficulties attending the former part of this, by what physical or astronomical catastrophe does he account for the latter? Wisely, he makes no attempt to indicate this.

Again, in speaking of the contents of caves, Mr. Howorth constantly lays stress upon the indications of the action of running waters, and upon the absence of any such disturbing agent at the present time. But he forgets that even followers of Lyell would admit that at no very remote epoch the climate of England was different, the rainfall was heavier, the streams were all bigger, nay, that a cave itself is symptomatic of running water, which in most cases would gradually forsake its old course. The stream which made Clapham Cave still runs concealed, hard at hand, through the limestone rock, and not so long ago, after a downpour on Ingleborough, welled up into its ancient channel. We wonder whether Mr. Howorth has ever seen what the fall of 4 inches of rain in a single night—no unprecedented case—can do even in our English lowlands. Such a downfall would turn many a dry fissure, small as its drainage-area might be, into a running stream. Mr. Howorth, in combating uniformitarians, seems to overlook the variations and catastrophes on a small scale (compared with the bulk of the earth) which everyone who has sat at the feet of Lyell accepts as axiomatic.

It would have been more politic had Mr. Howorth contented himself with local deluges ; but no, his destroying waves must pass over the whole earth. What is to generate these destructive waves, what multiplication of a Krakatão catastrophe is needed, how many cubic miles of mountain summit must fall into the sea, or of ocean bed leap up into the air, he forbears to tell us. Here, after a laborious scrutiny of facts, the reader is refreshed by a use of the imagination.

We leave a host of minor difficulties unnoticed for want of space, such as the occurrence of erratic blocks in positions of unstable equilibrium, the relation of drifts, supposed cataclysmal by the author, to the valleys in which they occur, the escape of apterous birds like the moa and the dodo, and the like. We must part from the book by saying that it exhibits great industry in the collection of materials—so that it will long be valuable as a work of reference—with a curious want of mental perspective, and a misapplied ingenuity of reasoning.

NEW ZEALAND SCALE INSECTS.

An Account of New Zealand Scale Insects. By W. M. Maskell, F.R.M.S. (Wellington : Geo. Didsbury, 1887.)

THIS book shows that the valuable work which is being done in South Australia by Mr. Frazer Crawford, Inspector under the Vine-Protection Act, is being done on a still greater scale in New Zealand. It affords an example of the great service which may be rendered by plain and sound publications on the subject of injurious insect attacks in the colonies. In the mother country the works which have been prepared for the Agricultural Department of the Privy Council by Mr. Whitehead, and Miss E. A. Ormerod's constant valuable publications on economic entomology, show what can be achieved in this field.

It is eminently satisfactory to find such an important subject taken up in New Zealand by an observer so well known as Mr. Maskell. The work extends to 116 pages, and includes exhaustive information on the Coccididæ affecting the crops of the island. The life-history of the Coccididæ (which are divided by the author as follows: I. Diaspidinæ; II. Lecanidinæ; III. Hemicoccidinæ; IV. Coccidinæ) is given in all its stages, a whole chapter being devoted to it, with descriptions of the male and female perfect insects in detail, and another to the natural checks to their increase, and parasites, &c.

The remedies against Coccididæ are fully treated of in Chapter V. The author gives a list of washes, of which he says: "Some of the substances here given are manifestly unsuitable for general use on account of their expense, at any rate in the open air; yet it is well to include them, as they are all suggested in some work or other, or in the replies of gardeners and fruit-growers to Parliamentary inquiries, and the objections to them ought to be known."

Chapter VI. is devoted to "A Catalogue of Insects"—that is, of the Coccididæ—and "A Diagnosis of Species," and will be found to be of great service to all students of entomology. Particular attention is paid to the cottony-cushion scale, the *Icerya purchasi*, whose ravages in South Africa have been so ably treated of in the pamphlet lately published by the Consulting Entomologist of the Royal Agricultural Society of England, also by the State Inspector of the Fruit Pests of California, and more recently by Prof. Riley, the well-known Entomologist of the Department of Agriculture of the United States. "Tree-growers should especially beware of this insect, and the best plan to adopt would be to burn at once any tree found infested with it."

This chapter, which occupies almost two-thirds of the book, is succeeded by an index of plants and the Coccididæ attacking them, with the useful reminder that in hot-houses and green-houses all sorts of plants are liable to attack.

The work also contains twenty-three well-drawn plates, which convey a good idea of the Coccididæ to those who have not the opportunity of studying them. Plates I., II., and III. deal with anatomical points or structural details; Plates IV. to XX. give a large selection of insects, with specimens of the various trees and plants they infest; Plate XXI. is especially valuable as giving the male insects *Cœlostoma zœlandicum* and *C. wairoense*, the antenna of the former and the head of the latter being especially well marked. Plate XXII. gives the honey-dew and resulting fungi, and Plate XXIII. parasites of Coccididæ. "Fig. 1, *a*, pupa of Hymenopterous parasites; *b*, the same pupa under the waxy test of *Ctenochiton perforatus*; *c*, imago. Fig. 2, *a*, brown and yellow fungi on *Ctenochiton viridis*; *b*, upper side of brown fungus; *c*, under side of the same, with attached fungoid sheet; *d*, *Ctenochiton viridis* (test removed), filled with yellow fungus, and with globular mass of the same above it."

From the above brief sketch of the contents of Mr. Maskell's book it will be seen that it is a welcome addition to entomological literature. It is written in plain and forcible language, and there is no padding or beating about the bush for the reviewer to find fault with. There is an excellent tabulated explanation of terms used, and students will be much pleased with the author's classification, or rather division or arrangement, of the Coccididæ, based upon a plan most useful for economic entomology:—

"Neglecting entomological distinctions, we may divide the Coccididæ roughly into

"(*a*) Insects attacking deciduous plants;
"(*b*) Insects attacking evergreen plants;

or again:

"(*c*) Insects living usually on the bark;
"(*d*) Insects living usually on the leaves;
"(*e*) Insects living on both bark and leaves;

or lastly:

"(*f*) Insects covered with hard shields or 'scales';
"(*g*) Insects covered with cotton;
"(*h*) Insects naked."

Among other salient points the importance of destroying the eggs is frequently urged upon those who wish to extirpate coccids, and attention is wisely drawn to the fact that "it is a fallacy to imagine that rule-of-thumb methods, not founded upon any knowledge of the nature, habits, and life-history of the insects, are likely to be really efficacious."

We agree with the author that an increase in works on

economic entomology is always of good service in any country, and New Zealand may be congratulated on having Mr. Maskell at hand to supply a demand generated by the improved intelligence of the agricultural community.

OUR BOOK SHELF.

Pen and Pencil in Asia Minor; or, Notes from the Levant. By William Cochran. Illustrated with eighty-nine engravings, made chiefly from water-colour sketches by the Author. (London: Sampson Low and Co., 1887.)

THIS well-printed volume of over 450 pages is one of a class that we had thought had become extinct. The notes begin with the arrival of the author at the Alexandra Docks in Liverpool, and are continued almost daily, in some instances hourly, until the close of a five-months' tour through the Mediterranean to Smyrna, Constantinople, and then, with some slight journeys inland, back again by the same route to Liverpool.

No doubt the journey was pleasant, and we feel sure that the note-taking and the water-colour sketching were very agreeable occupations for the tourist; but probably even the author's friends would admit that as now laid before the world the text contains nothing either very novel or attractive, while of the many scenes sketched, omitting the sketches from photographs, we may say that it would be hardly fair to criticize them from an art point of view. The volume is not, however, without its merits. The author deserves credit for the earnest way in which he has called attention to the importance of encouraging the tea and silk industries, and we sincerely hope for the good of our colonies that his efforts in the direction of silk culture in Australia and New Zealand may eventually be as successful as tea-farming has been in Ceylon.

One chief object of the voyage to Smyrna was to see the result of Mr. John Griffitt's silk-farming in Asia Minor. At one time the silk industry was one of great importance in and about Smyrna, but owing to the silk-worm disease it became almost extinct, so that even the very mulberry-trees were used for firewood. Now, through the philanthropic zeal of Mr. Griffitts in supplying silkworm eggs not only free from disease but raised from carefully-selected varieties, the industry is being restored, and large numbers of mulberry-trees are being planted.

Several chapters in this volume are devoted to the subjects of the rearing of silkworms, and of the treatment of the mulberry-trees. From the hatching out of the larval forms to the reeling off of the silk, only some forty to forty-five days elapse, but though the labour be short, the care and attention required are very great, and the successful silk rearer learns various lessons of method and cleanliness which are of permanent value.

In chapter ix. we have a summary of Mr. Griffitt's valuable report on the silk trade, furnished to the Department of State, Washington. From it we learn that at one time in Smyrna there were three large silk-reeling factories, driven by steam, where hundreds of female hands were employed. When, on the failure of the indigenous worms, Japanese worms were introduced, it was found that it required double the number of cocoons to yield the same weight of silk. With Mr. Griffitt's improved native race of silkworms, the quality of the silk is better, and the produce much heavier than before. To those interested in silk culture we can recommend the perusal of this volume, which, indeed, would be better described as "Notes on Silk Culture in Smyrna."

A Catalogue of the Flora of Matheran and Mahableshwar. By the Hon. H. M. Birdwood, M.A., LL.M. With a Note by Dr. Theodore Cooke, LL.D., F.G.S. (1887.)

THIS little botanical work is a reprint from the Journal of the Bombay Natural History Society. It will be useful to persons visiting the localities botanized; and the records of the upper limits of various plants are interesting to botanists at a distance.

Mahableshwar is in the Ghauts, about a hundred miles south of Bombay, and the highest part of this healthy resort is nearly 5000 feet above sea-level, so that there are considerable changes in the vegetation in the ascent. The present catalogue contains the names of less than 500 species of plants, a number which future investigations will doubtless double. As the Bombay Natural History Society is still in its infancy, some singular slips in the classification of the plants are perhaps excusable; and we hope the members will not feel discouraged at our pointing out that ferns are not "plants with cellular tissue only," nor are mosses "leafless plants."

The Bombay Natural History Society possesses a herbarium of Mahableshwar plants, presented to it by Dr. Cooke, and it may be hoped that this will form the nucleus of a collection adequately representing the whole flora of the entire Presidency. Up to the present time the Bombay Government has shown but little interest in botanical work, and possesses none of the appliances for its prosecution to be found at Calcutta, Saharunpore, Madras, or Peradeniya. Yet for the Forest Department alone some kind of herbarium and botanical library is indispensable, unless its officers are to grope in the dark as to a large proportion of the plants they come across in their duties.

However, this is by the way. It is a sign of the development of a healthier interest when a hard-worked official like a judge of the High Court is found to take the lead in so creditable a way in the study of the local flora.

L'Homme avant l'Histoire. Par Ch. Debierre. (Paris: J. B. Baillière et Fils, 1888.)

IN this book M. Debierre gives a clear and interesting account of some of the results of anthropological research. In dealing with disputed points, however, he is apt to arrive at conclusions somewhat hastily. The doctrine of the unity of the human race he rejects, but he contents himself with a very slight and inadequate consideration of the arguments which may be advanced on the other side. Again, he assumes that there can be no doubt whatever as to the Asiatic origin of the Aryan or Indo-European race. That the original home of the Aryans was in Europe cannot be held to have been proved, but the theory has been accepted by so many investigators, and so much may be said in favour of it, that in a work of this nature it ought at least to have been explained and discussed.

Philips' Handy Volume Atlas of the British Empire, with Statistical Notes and Index. (London: Philip and Son, 1887.)

THIS little book is among the first British work of its sort that we have seen. It is extremely neatly put together and is well edited throughout. It contains 64 plates and on them 110 maps, showing the British possessions in the various parts of the globe. After each map is a short analysis of position, extent, population, climate, industries, government, orography and hydrography, &c., &c. In addition to the maps there are plans of various towns. Just before the index are given "Comparative Diagrams of the British Empire," comparing area, population, trade, and revenue of the British possessions of the different quarters of the globe. This is followed by the

index itself, with a list of abbreviations, consisting of twenty pages closely filled in with places in three columns. The colouring of the maps is excellent, and it is obvious that no attempt has been spared to make the book as complete as possible in every way. A. L.

The Young Collector's Hand-book of Ants, Bees, Dragon-Flies, Earwigs, Crickets, and Flies. By W. Harcourt Bath. (London: Swan Sonnenschein, 1888.)

ANY boy who may wish to form a collection of insects will find in this little hand-book all the information he will be likely to need at first for his guidance. The author does not pretend to go deeply into the subject, but he has brought together a sufficient number of facts to show beginners that the study of entomology will well reward any labour that may be devoted to it. His explanations are simple and clear, and the value of the manual is much increased by a large number of good illustrations.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

An Earthquake in England.

AS no account has been given in NATURE of a recent earthquake, perhaps room may be found for the following. I was standing near my garden door at 8.20 a.m. on Sunday, November 20, when the quiet was suddenly broken by a heavy smothered crash, followed by reverberations as in a clap of thunder of rather short duration. I felt no shaking of the ground, but many persons here felt it, and the shaking is stated to have been very marked near Dagnall, between here and Hemel Hempstead. The sound was like the falling in of an immense mass of rock—followed by echoes—in a cavern.

Some persons say they heard a second, but much less loud, crash later in the morning, but this was not heard by me.

At Ampthill, near Bedford, persons left the town to meet the first train from London to inquire of the passengers as to a possible explosion having occurred in London.

The crash was heard in Bucks, Beds, Herts, Suffolk, Essex, Cambridge, and possibly in other counties. I have seen reports from Newmarket, Hitchin, Cambridge, Wimpole, Heydon, Royston, and Saffron Walden, in addition to accounts from many positions close to this place.

It is curious that Stow records, under A.D. 1250, the thirty-fourth year of the reign of Henry III.:—"Upon St. Lucie's Day, there was a great earthquake in this town (St. Albans) and the parts thereabouts, with a noise underground as tho' it thundered, which was the more strange for that the ground is chalky and sound, nor hollow or loose as those are where earthquakes often happen; and this noise did so fright the daws, rooks, and other birds which sat upon houses or trees, that they flew to and fro, as if they had been frighted by a gosshawk." WORTHINGTON G. SMITH.

Dunstable.

On the Constant P in Observations of Terrestrial Magnetism.

THE formula for P given by Mr. Rücker (NATURE, vol. xxxvi. p. 508) has evidently been obtained by expanding the usual expression rigorously to terms of the second order; but as the usual expression differs from Gauss's theory by terms of the second order, Mr. Rücker's expansion is necessarily inexact to the same extent, and in fact his second order term has no existence in Gauss's theory.

Going only to terms involving r^{-5}, Gauss's equations may be written—

$$f(u) = \mathrm{L}r^{-3} + \mathrm{L}^1 r^{-5} \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

$$f(u_1) = \mathrm{L}r_1^{-3} + \mathrm{L}^1 r_1^{-5} \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

$$\frac{m}{\mathrm{H}} = \tfrac{1}{2}\mathrm{L}\left(1 + \frac{\mathrm{S}}{\mathrm{F}}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where $f(u)$ signifies either sin u or tan u according to the form of instrument employed.

By putting

$$\mathrm{A} = \tfrac{1}{2}r^3 f(u) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

$$\mathrm{A}_1 = \tfrac{1}{2}r_1^3 f(u_1). \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (5)$$

$$\mathrm{B} = \frac{r_1^2 r^2}{r_1^2 - r^2} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (6)$$

we find from (1) and (2) respectively

$$\tfrac{1}{2}\mathrm{L} = \mathrm{A}\left\{1 - \mathrm{B}\left(\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}}\right)r^{-2}\right\} = \mathrm{A}\,(1 - \mathrm{P}r^{-2}). \quad (7)$$

$$\tfrac{1}{2}\mathrm{L} = \mathrm{A}_1\left\{1 - \mathrm{B}\left(\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}_1}\right)r_1^{-2}\right\} = \mathrm{A}_1(1 - \mathrm{P}_1 r_1^{-2}) \quad (8)$$

Whence, by inspection,

$$\mathrm{P} = \mathrm{B}\left(\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

$$\mathrm{P}_1 = \mathrm{B}\left(\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}_1}\right) \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (10)$$

To find $\tfrac{1}{2}$L we may use either (4) and (9), or (5) and (10); and in either case the result will be as accurate as our fundamental expressions.

Expanding (10) to terms of the second order,

$$\mathrm{P}_1 = \mathrm{B}\left(\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}}\right) + \mathrm{B}\left(\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}}\right)^2 \quad . \quad . \quad . \quad (11)$$

and therefore the mean of (9) and (10) is

$$\mathrm{P}_0 = \mathrm{B}\left\{\left(\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}}\right) + \frac{1}{2}\left(\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}}\right)^2\right\} \quad . \quad (12)$$

whence, by putting

$$\mathrm{C} = \log \mathrm{A} - \log \mathrm{A}_1$$

and remembering that

$$\frac{\mathrm{A} - \mathrm{A}_1}{\mathrm{A}} = \frac{\mathrm{C}}{\mathrm{M}} - \frac{\mathrm{C}^2}{\lfloor 2\mathrm{M}^2} + \frac{\mathrm{C}^3}{\lfloor 3\mathrm{M}^3}, \text{ \&c.} \quad . \quad . \quad . \quad (13)$$

in which M is the modulus of the common system of logarithms, we have to terms of the second order—

$$\mathrm{P}_0 = \frac{r_1^2 r^2}{r_1^2 - r^2}\left\{\frac{\log \mathrm{A} - \log \mathrm{A}_1}{\mathrm{M}}\right\} \quad . \quad . \quad . \quad (14)$$

Equation (9) is what I gave in my letter on p. 366 of the last volume of NATURE, where I was careful to say that it was derived from Gauss's original equations. When properly used it is as accurate as equations (1) and (2). Equation (14) was given by Mr. Ellis in his letter on p. 436. It is slightly easier to compute than (9), and differs from that expression by a term of the second order which is less than the accidental error of observation. The second order term added by Mr. Rücker renders his expression less accurate than either (9) or (14), if Gauss's theory is accepted as correct. WM. HARKNESS.

Washington, D.C., November 4.

I THINK that on reconsideration Prof. Harkness will admit that it is not I who have fallen into error. If only two observations are made, equations (7) and (8) are identical, and there is no need for the introduction of P_0. In like manner if numerous measurements were available in which the error of observation was *nil*, any pair would give the same value of L, and P_0 would again be unnecessary. If, however, the equations are affected by errors of observation, and it be agreed that in combining them we may replace the P's by a single quantity, P_0, it must not be arbitrarily defined. Prof. Harkness assumes that in the case of two observations it must be the mean of P and P_1, but he gives no reasons, and he does not state what value he would adopt if

the measurements were numerous. The proper course is to determine it by the method of least squares.

Writing f for $f(u)$ and omitting $1 + \frac{S}{F}$, (3) may by the aid of (7) be written in the form—

$$\frac{1}{f} = \frac{H}{2m}(r^3 - P_0 r).$$

This is exactly analogous to the equations used by Maxwell in the determination of the quantity A_2, which in his notation and method of development corresponds to P_0 ("Electricity and Magnetism," second edition, vol. ii. p. 100). It is unnecessary to occupy the pages of NATURE with a reproduction *mutatis mutandis* of his formulæ. We can get, as he does, a general expression for P_0 when we have n equations at our disposal, and when $n = 2$ this reduces (in the notation of Prof. Harkness) to—

$$(\alpha) \qquad P_0 = (A - A_1)/(A/r^2 - A_1/r_1^2).$$

If then in a magnetic survey observations are made at two distances at a number of stations, we should take as the final value of P_0 the mean of the most probable values found at each station. As this would be unduly laborious, we approximate. By an obvious transformation (α) becomes—

$$\log\left(1 - \frac{P_0}{r_1^2}\right) - \log\left(1 - \frac{P_0}{r^2}\right) = \log A - \log A_1$$

$$\therefore P_0(r^{-2} - r_1^{-2}) + \frac{P_0^2}{2}(r^{-4} - r_1^{-4}) + \&c. = \frac{\log A - \log A_1}{M}.$$

Thus to a first approximation—

$$(\beta) \qquad P_0 = \frac{r^2 r_1^2}{r_1^2 - r^2} \cdot \frac{\log A - \log A_1}{M}.$$

And if we substitute this value in the small term—

$$(\gamma) \qquad P_0 = \frac{r^2 r_1^2}{r_1^2 - r^2} \cdot \frac{\log A - \log A_1}{M}$$

$$- \frac{r_1^2 r^2}{2} \cdot \frac{r_1^2 + r^2}{(r_1^2 - r^2)^2} \left(\frac{\log A - \log A_1}{M}^2\right).$$

This is the expression I gave. The effect of the small term in (γ) is, as I pointed out, less than the error of experiment, but it diminishes the difference between the rigorous and approximate values of P_0 given in (α) and (β), and it is useful in indicating the magnitude of the difference between them.

Fortunately all methods lead to (β) as a first approximation which we are agreed is close enough for practical purposes. If, however, we regard the observations as fallible, (α) gives a better value of P_0 than (14), and equation (γ) gives a closer approximation to it than (β) does. ARTHUR W. RÜCKER.

Science Schools, South Kensington, November 24.

P.S.—It may be well to add that, although the formula for A_2 is correctly given by Maxwell in line 17, p. 101, the value of A_2 deduced below is incorrect, being really that of $2MA_2/H$. There is another misprint immediately below, δD being substituted for δQ in the second edition.

Instability of Freshly Magnetized Needles.

I SHOULD like to be permitted to support Prof. Rücker in his reply to Prof. Nipher (NATURE, vol. xxxvii. p. 77), with a few remarks on the subject of observations of magnetic dip.

The question of the degree of accuracy of dip observations is one that has been repeatedly raised and discussed. In 1864 in his report to the Board of Visitors, the Astronomer-Royal, Sir G. B. Airy, referred to the matter, and a correspondance between him and the Chairman of the Kew Committee (Mr. L. P. Gassiot) ensued, which is printed *in extenso* in the Report of the British Association for 1864, pp. xxxiv.-xlvii.

In reply to an inquiry by Mr. Gassiot as to whether the paragraph in the Report was intended to apply to dip observations made at the Kew Observatory, Sir G. B. Airy quoted the following statement by Sir E. Sabine :—"The probable error of a *single observation of the dip* with reliable instruments of easy procurement is known to be ± 1'·5. It has been shown to be so by a series of 282 observations made at Kew, employing twelve circles and twenty-four needles, all of the pattern which has been in use at Kew for several years past. The observations were made by seven different observers; the results are published in the Proceedings of the Royal Society, March 1861, vol. xi. p. 156, from entries in the Kew Observatory books, not a single observation having been omitted. The probable error ± 1'·5 may be regarded as including *constant* errors, considering the number of different circles and needles which were employed, as well as the peculiarities of different observers, of whom there were seven" (the italics are General Sabine's). The Astronomer-Royal then concluded by stating "these are the probable errors which I cannot accept as accurate."

As a result of the correspondence, a series of observations was made at both the Greenwich and Kew Observatories by the observers of both institutions, with the same Kew pattern instruments, and then Sir G. Airy wrote, in a letter dated November 15, as follows: "As regards the results of observations, those made with the Kew instruments are consistent to a degree which I never saw before; and the results for dip obtainable with the Kew dip instruments are undoubtedly more consistent and more certain than I had supposed them to be."

A similar inquiry was set on foot by Dr. H. Wild, of St. Petersburg, and in 1886 we made a large number of observations with different needles for him, the resulting error of an observation being in this case ± 1'·3. The most severe test, so far as we are aware, which has been applied to dip observation, is that recently described by M. E. Leyst, of St. Petersburg, in a quarto volume of 133 pages, published in the *Repertorium für Meteorologie*, entitled "Untersuchung über Nadel Inclinatorien."

The author discusses some 6576 observations of dip made with different instruments and needles, and determines their probable errors, which he always find small, so much so that he deduces the corrections to hundredths of a minute of arc. To quote particular cases, he determines from thirty series of comparisons between observations and the simultaneous readings of the magnetographs and the induction inclinometer, that the difference amounts to only 1'·06; and again, by comparing at Pawlowsk the fifteen needles of the three dip instruments of the Pawlowsk, Irkutsk, and Ekaterinburg Observatories (all of English make, obtained through this Observatory), he finds their mean correction to be nil.

Judging from the experience gained at Kew by the examination of probably 150 circles and 500 needles by various makers and different observers, I can thoroughly indorse Prof. Rücker's opinion that Prof. Nipher's instruments are scarcely capable of satisfying modern requirements as to accuracy, and are such that were they submitted to us for examination they would be promptly returned to their makers for adjustment.

G. M. WHIPPLE.

Kew Observatory, November 26.

Gore's Railway.

As I have had several letters concerning my use of Dr. Gore's arrangement, depicted on p. 107 of your last week's issue, perhaps I may as well say that I am aware it is commonly regarded as a Trevelyan rocker, and that I doubt not its function in that connection. This point of view is so familiar to every one, through Tyndall's "Heat," that I thought it unnecessary to mention it. But I have occasionally heard the motion of the ball attributed to the electro-magnetic action of the current on itself—which is impossible—and I thought it useful to point out that it could nevertheless be used as an illustration of electromagnetic force, provided a vertical magnetic field is applied as well as a current. I should imagine the earth not too weak to have an effect under favourable conditions; but of course such an effect would be strictly definite in direction, and reversible.

OLIVER J. LODGE.

The Highclere Bagshots.

THE notice in NATURE for December 1 (p. 104), by my friend Mr. R. S. Herries, of casts of shells in the Bagshot Beds at Highclere tends strongly to confirm the results of my own work in that district. On the strength of physical and stratigraphical evidence, I have shown the development in that neighbourhood of *all the three stages* of the Bagshot formation

as we know it in the London Basin. This will be seen on the publication of a paper which was sent in to the Secretary of the Geological Society on October 10 last, but has not yet been put down by the Council for reading. A. IRVING.

Wellington College, Berks, December 2.

The Ffynnon Beuno and Cae Gwyn Caves.

MR. WORTHINGTON G. SMITH's letter in NATURE of December 1 (p. 105), is so misleading that I hope I may be allowed to reply to it. As is usual with highly prejudiced observers, he has attempted to prove too much for his case, as he might have seen had he taken the trouble to refer to my papers. The scraper which he mentions was submitted to Dr. John Evans for his opinion, and his conclusion as given in my paper in the Proceedings of the Geologists' Association, vol. ix. p. 17, is as follows. The scraper "is not of a river-drift form, so far as at present known, but is precisely like many from the French caves of the reindeer periods, such, for instance, as La Madelaine." Mr. Worthington Smith's contention therefore that it agrees exactly with "the Neolithic scrapers of Icklingham and Mildenhall" can only prove that there is no chronological value in the classification of such implements. I must explain, however, that we have based no argument on the scraper referred to, since it was found, before the explorations were properly commenced, in an open part of the cavern, and, as stated by me in the paper referred to, "it would be improper to dogmatize on this evidence." I may say at once that I entirely demur to any classification based on the form of the implements rather than on the fauna associated with them, and I see no reason whatever to suppose that the worn, roughly-trimmed implements usually found in river gravels are older than the better-preserved flakes and trimmed implements found in caverns, which would be used for a different purpose from the rougher ones. The implements discovered subsequently belong to the so-called oldest types found in caverns, and were associated with Mammalian remains, equally characteristic of the oldest river gravels as of the caverns. Mr. Smith's statements in regard to the drift "in front of the Denbighshire caves" are of so extraordinary a character that I am tempted to ask him, before I criticize those statements, whether he ever visited the Ffynnon Beuno Caves during the course of the explorations, whether he ever saw the section of the drift exposed at the Cae Gwyn Cave, and what evidence he can bring forward to support his statements that the drift "is not in its original position, but distinctly and obviously relaid," and that he doubts "whether before it was relaid it was a true Glacial gravel at all?" I think the members of the British Association Committee, who have carefully conducted the explorations, and have the strongest evidence in support of their conclusion that the caverns, which are now about 400 feet above sea-level, were occupied by man and the animals before the marine drift and boulder-clay covered them over, have a right to ask for the data upon which such statements as those above referred to are based. These relate to facts, and must be dealt with in a different manner from those statements which are made clearly from a bias against the idea of Glacial and pre-Glacial man. Mr. Smith says that he has not been able to read up the literature of the subject, therefore he is probably unaware of the fact that Prof. Prestwich has recently (Quart. Journ. Geol. Soc. for August last) stated that he has arrived at the conclusion that the high-level gravels, with implements, in the valleys of the Somme, Seine, Thames, and Avon date back to Glacial or pre-Glacial times; and that "the great masses of gravel in the neighbourhood of Mildenhall and Lakenheath, also containing flint implements, are certainly not of fluviatile origin"; and that they seem to him "to be part of the phenomena connected with the passage of the great ice-sheet over the eastern counties, and in that sense pre-Glacial." HENRY HICKS.

Hendon, December 2.

Cloud Movements in the Tropics, and Cloud Classification.

A FEW months ago I called attention to the fact that the general movement of the upper clouds in the tropical regions of the Atlantic was from a westerly point; since then I have worked up all my observations (which extend over a period of 331 days spent in these regions in all months of the year except June) with the following results:—

Between latitudes	Upper layer of cloud comes from	Middle layer of cloud comes from
N. 23° and 17°	S. 67° W.	S. 45° W.
N. 16° ,, 11°	S. 56½° W.	S. 83° W.
N. 10° ,, 6°	S. 1° W.	S. 17° W.
N. 5° ,, 0°	N. 41° W.	N. 35° E.
S. 1° ,, 5°	N. 32° W.	N. 78° E.
S. 6° ,, 10°	N. 45° W.	S. 58° W.
S. 11° ,, 15°	N. 53° W.	N. 16° W.
S. 16° ,, 23°	S. 86° W.	N. 55° W.

Taking a general mean for the whole region, this gives for the upper layer of clouds N. 86½° W., and for the middle layer of clouds S. 73° W. These results are from observations taken by myself, and no observation was registered if there was the slightest doubt as to the cloud movement. The ordinary ship register of upper cloud movements is worse than useless, a propagatory movement of the upper clouds being constantly mistaken for their real movement, and the names being hopelessly mixed, the cirro-cumulus being the source of most mistakes.

The cirro-cumulus exceeds all other forms of cloud in extent, ranging from the delicate fine mottles at a great elevation to the large flaky masses quite low down, and until it is considered a middle layer cloud we are certain to have some confusion.

It is quite time that cloud classification was placed on a more satisfactory basis. Now one observer will call a certain form of cirro-cumulus, a cumulo-cirrus; a moderately high (middle layer) stratus of uniform texture, a cirro-stratus; again, one form of low stratus, a pallio-stratus. Another observer will even call a detached fragmentary stratus, cirro-cumulus; and lots of observations will be useless from one observer failing to understand the particular form of cloud A calls pallio-stratus or B calls cirro-cumulus. Far better to keep to Luke Howard's simple nomenculature till some classification is definitely fixed to which all can agree.

To be satisfactory the classification must be founded on the physical and morphological (if I may use the word here) structure of clouds. I find no difficulty in making observers understand the difference between a stratiform and a cumuliform cloud; this is the first step, and once the distinction is thoroughly grasped the rest is comparatively easy. I propose something of this sort. Two orders, the "Stratiforms" and the "Cumuliforms," these to be subdivided into types, and these again into species; *e.g.* taking the ordinary dull-looking stratus commonly seen in anticyclonic areas, it would be described as—

Order	...	Stratus.
Type	...	Low-stratus.
Species	...	Pallio-stratus.

Or take that form of cirrus which appears as lines or threads right across the sky; it would be destribed thus—

Order	...	Stratus.
Type	...	Cirrus.
Species	...	Cirro-filum.

By using this system an observer would be gradually brought to recognize first the broad distinctions and then the minute distinctions in clouds. DAVID WILSON-BARKER.

THE FORMS OF CLOUDS.

SO much attention has been given of late years to the study of clouds, and so many names have been suggested by different writers for the same form of cloud, that the whole question of cloud forms and cloud names must soon be referred to an International Congress. A few remarks on certain broad facts connected with the shapes of clouds, and on the fundamental principles by which weather forecasts are deduced from these forms, may therefore be acceptable to those who have not given special attention to the subject.

The two most important facts which must never be forgotten are: (1) that cloud forms are essentially the same all over the world; and (2) that there are only five or six distinct structures of clouds.

The identity of cloud forms all over the world has recently been demonstrated both before the Royal Society and the Royal Meteorological Society of London by the exhibition of about fifty photographs of clouds taken by the writer in various longitudes, and in latitudes ranging from 72° N. to 56° S. Some of these are reproduced in the illustrations of this article, and the conclusion of identity is irresistible. The cirrifying cloud over an irregular cumulus, in Fig. 3, might be seen over any summer thunderstorm in England, though this example is from tropical Borneo; while the fleecy cirro-cumulus in Fig. 4, which was taken near the Falkland Islands, about 51° S., differs in no respect from the similar cloud we so often see at home. Fig. 6 is a strato-cumulus from near Teneriffe, in the heart of the North-east Trade; but the writer has seen an absolutely identical sky from the summit of North Cape, far within the Arctic Circle.

Fig. 1.—Cirrus wisp over cumulus. Folkestone.

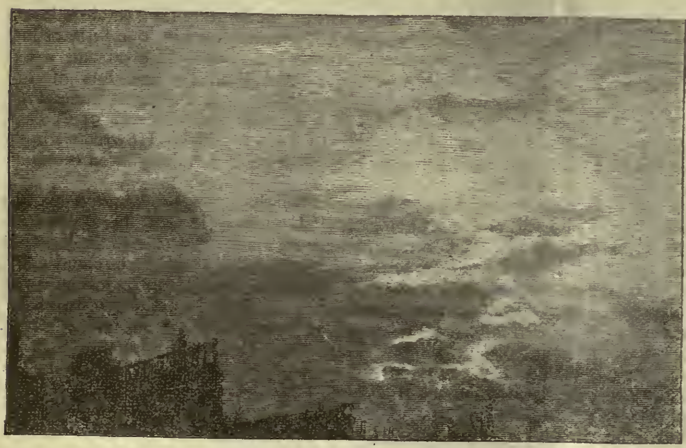

Fig. 2.—Stratus. London

Fig. 3.—Cumulo-nimbus, cirrifying above. Borneo.

The different structures of clouds can certainly be reduced essentially to five or six types. A great deal must of course depend on the definition we adopt of a kind or species of cloud. We believe that one German meteorologist in Rhineland says that he has discovered 30,000 different kinds of cloud, and that he has not yet finished his classification. This is absurd; for though no two clouds are ever exactly the same, any more than any two faces, still certain broad types of cloud structure can readily be recognized.

The first primary type of structure is the cirriform or hairy. The thin fibres of white silvery cloud which constitute a cirrus may assume an almost infinite variety of forms. The commonest is the simple wisp of white threads such as is shown in Fig. 1, floating at a high level over a heavy mass of cumulus cloud. Sometimes the cirrus lies in long straight stripes, which Ley has shown have a great value in forecasting weather; or at other times assumes the "penniform" or plume-like appearance which, according to Vines, precedes a hurricane in the Antilles.

Cirrus as a rule is formed at very high levels—20,000 to 25,000 feet—and the constituent particles are undoubtedly frozen, but we occasionally find a fibrous structure at low levels, where the constituent particles are certainly in a fluid form. Both the cirrus and cumulus in Fig. 1 are composed of icy particles, for the picture was taken on a cold winter day in England when snow showers were flying about. But in Fig. 3 we see a fibrous combed-out structure at quite a low level in Borneo, where the temperature both of the air and the rain makes it certain that the whole cloud mass was made up of liquid particles.

The true cumuloform structure of cloud can never be mistaken. The rising mass of condensed vapour assumes a rocky, lumpy appearance, which is well delineated in the lower portion of Fig. 1. The varieties of form are infinite. Sometimes beautiful little isolated cloudlets, each with its own flat base, float all over the sky, while at other times we only see mountainous masses rising above a gloomy cloud bank on the horizon, as in Fig. 3.

Essentially different from the above is the stratiform structure which is depicted in Fig. 2. Here we have a thin layer of flat cloud, at low level, more or less broken, but showing no trace of either a fibrous, rolled, or lumpy structure. When the sky is broken, this form of cloud is unmistakable, but when overcast it is impossible to dis-

tinguish pure stratus from the flat under surface of some kinds of cumulus or nimbus.

The term nimbus is applied to any cloud which is precipitating rain. In practice we find two rather distinct types—a strato-nimbus or flat cloud, and a cumulo-nimbus or rocky rain-cloud. The former is characteristic of the rainfall in front of an extra-tropical cyclone, the latter of the precipitation from squalls and thunderstorms all over the world. Our illustration (Fig. 3) represents a distant view of the clouds over a thunderstorm in Borneo. Below we see the rocky summits of a mass of cumulo-nimbus, while apparently above, but really at about the same level, we find the characteristic fibrous structure that is called "goat's hair" by some, or "false cirrus" by others.

Another typical structure is that which has been called in all times by all nations fleecy, woolly, or some cognate name. In this, clouds assume the appearance of a fleece of wool. Each little mass of condensed vapour has a peculiar fibrous structure, quite different from true cirrus. The density and level of formation vary a good deal. When the cloud is thin at up to about 25,000 feet, most meteorologists call it cirro-cumulus; but when denser, and down at about 18,000 feet, the name of cumulo-cirrus has been proposed to distinguish this low variety. Fig. 4 is an excellent specimen of cirro-cumulus, from a photograph taken near the Falkland Islands

There is a form of cloud intermediate between pure cirrus and pure stratus which is so common and so characteristic of bad weather that it has universally been classified as cirro-stratus. We apply the term to a sky which is covered with a thin layer of cirrus fibres, more or less mixed up with a formless haze or veil of scattered ice-particles. Sometimes the cirrus threads are thin and white as the finest gossamer, and float 25,000 to 27,000 feet above the earth, but at other times the structure is coarser, and the level of formation not more than 18,000 feet. The first kind is called cirro-stratus, the second strato-cirrus. Fig. 5 is an example of a rather heavy cirro-stratus, taken near Dover. It will be observed that there are two distinct lines of structure about which the cloud masses are grouped, and that the lines intersect one another at a certain angle, so that the whole has a certain reticulated appearance. This is most characteristic of cirro-stratus.

Cirro-stratus with its hairy structure, and cirro-cumulus with its fleecy appearance, might at first sight appear to be radically different from one another; but they are not so really. It is by no means uncommon to see a patch of fibrous cirro-stratus suddenly become fleecy for a few minutes, and then return again to its former state. We cannot give the reason for this, as the origin of both structures is at present unknown.

There is a form of cloud, intermediate between stratus and cumulus, to which the word strato-cumulus is appropriately applied. In this the cloud layer is too lumpy to be called pure stratus, and not rocky enough to be called cumulus. Fig. 6 is an excellent specimen of this type, taken near Teneriffe; and here we see the lumpy masses of cloud getting apparently thinner and thinner as they approach the horizon, till they look at last like a series of stripes or rolls parallel to the horizon. This of course is the result of perspective.

Fig. 4.—Cirro-cumulus, or fleecy structure. Falkland Islands.

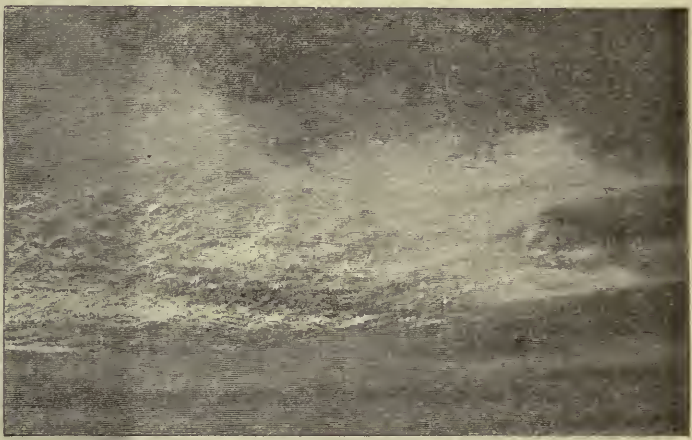

Fig. 5.—Cirro-stratus. Folkestone.

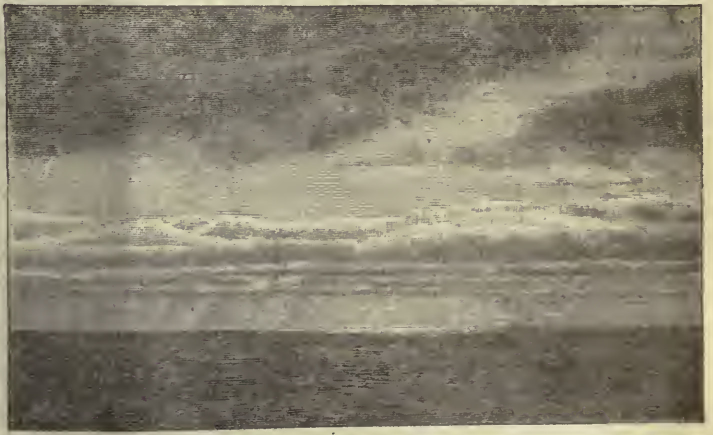

Fig. 6.—Strato-cumulus. Near Teneriffe.

The ten varieties of cloud which we have now described

—cirrus, cumulus, stratus, nimbus and cumulo-nimbus, cirro-cumulus and cumulo-cirrus, cirro-stratus and strato-cirrus, together with strato-cumulus—comprise all the important kinds of clouds; and there are really only five distinct types of structure—cirrus, stratus, cumulus, nimbus, and cirro-cumulus. Prof. Hildebrandsson and myself consider that the ten words above mentioned, compounded out of only four Latin words, are practically sufficient for all ordinary purposes.

Specialists in clouds will of course want more minute varieties, such as different names for some of the kinds of cirrus, and for the low broken clouds, such as scud, wrack, &c. There are also a whole class of pendulous clouds, such as festooned stratus, pocky cloud, or mammato-cumulus; and the long black wreaths of cloud in front of certain types of thunderstorm, but these are all very local, and also very short-lived, so that they need only be mentioned here.

So far for the mere external forms of clouds as they would strike a savage or an artist; but to the meteorologist there is a philosophy behind them. In England some forms presage wind and rain, others indicate the advent of fine weather; while recently it has been shown that different kinds of clouds are developed in different parts of cyclones and anticyclones. For instance, cirro-stratus forms in front, cumulus in rear, of a cyclone; while fleecy cirro-cumulus is very characteristic of the western side of the anticyclones.

But then we are met by the apparent paradox that precisely the same forms of cloud are found on the equator where neither cyclone nor anticyclone was ever developed. Moreover, the same cloud does not prognosticate the same weather all over the world, and even in the same country the same cloud may indicate either good or bad weather according to the circumstances under which it is developed. For instance, cumulus in England is sometimes the associate of a fine day, other times the forerunner of a shower.

The clue to the whole puzzle lies in the fact that the same form of cloud can be produced under totally different circumstances. Vapour-laden air can only condense into cloud, and then be drawn out or rolled about between different currents in a very limited number of ways, and hence the small number of really distinct varieties of cloud structure.

Let us take the case of cumulus in detail as an example of general principles. Cumulus is always the condensed capital of an ascensional column of air, but the source of the uptake need not always be the same. For instance, air may rise either (1) from ordinary evaporation on a fine day; (2) from the uptake of a cyclonic vortex; (3) from the collision between two opposite currents.

The first—evaporation—is the source of fine-weather cumulus in England and all over the world; while the uptake of a cyclone is the cause of rainy cumulus wherever such eddies are formed. The rainy cumulus of the equator is the product of squalls and thunderstorms whose nature at present is unknown in most cases; but one very common cause is the collision between the land and sea breezes of the tropics. The two opposing currents meet, one is forced upwards, and then mountainous cumulus is the result. The cumulo-nimbus in Fig. 3 is over a thunderstorm in Borneo, due to the collision of the land and sea breezes.

All, therefore, that we can say for certain when we see a cumulus cloud is that an ascensional current of air has risen to the level of condensation. What future weather the cloud prognosticates depends on circumstances, and must be judged by our experience and knowledge of the climate in which we may happen to be. Clouds always tell a true story, but one which is hard to read; and the language of England is not the language of Borneo. The form alone only shows that a certain form of condensation is taking place; the true import must be judged by the surroundings, just as the sense of many words can only be judged by the context.

RALPH ABERCROMBY.

FIFTH ANNUAL REPORT OF THE FISHERY BOARD FOR SCOTLAND.

THE Report for 1886 contains so much of general interest that it deserves the attention of many who look upon a Blue-book as the driest of reading, only attractive to those whom it may immediately concern. It is desirable that the scope and practical aims of the Board should be more generally known, and the public should appreciate the excellent work done by it, instead of regarding this as the mere outcome of scientific leanings to certain lines of investigation. The fisheries of Scotland continue to be very productive, and nothing is more striking about them than the great and increasing yield of the herring fishery. Though this increase and the low price at which the herrings have been sold have proved a great boon to the community, especially to the poorer classes, it is deeply to be regretted that the crews sustained very heavy losses from the glutting of the market consequent on the large takes and low prices. A striking feature of the summer herring fishery of 1885 was that many in-shore grounds where herrings had been found in great abundance in previous years but which had been recently all but deserted were restored to their former fertility. This was even more marked in the season of 1886, as all along the east coast from Montrose to the Pentland Firth there seemed to be one immense unbroken shoal of herrings, lying from one to ten miles off land. At no former period in the history of this fishery were the catches so heavy. The winter herring fishery on the east coast was the most productive ever known, yielding a total catch of 128,441 crans. The gross total value of the sea and salmon fisheries of Scotland for 1886 was £2,550,778 8*s*. 3*d*.

During the past year the scientific work consisted chiefly in carrying on the trawling experiments required by the recent Act of Parliament (Sea Fisheries (Scotland) Amendment Act, 1885), but in addition investigations were made as to the development, artificial hatching, structure, and habits of the more important useful fishes. An important part of the inquiry as to the influence of trawling consisted in arranging to obtain statistics showing the quantities of fish landed from the restricted areas, and the conditions under which they were captured—an extremely difficult matter to arrange.

The Board's marine station at St. Andrews has again been under the direction of Prof. McIntosh, whose Report shows that important work on the life-histories and development of the food-fishes has been done at this station by him and Mr. E. E. Prince, by Dr. Scharff on the intra-ovarian eggs of food-fishes, and by Mr. Wilson on the development of the common mussel. The memoir first mentioned, viz. that on the development and life-histories of the food-fishes, is now ready for publication, and is illustrated by thirty-one quarto plates. Its size and the nature of the illustrations of course render it unsuitable for a Parliamentary Blue-book.

The "Report on the Trawling Experiments on the East Coast, Part I. Preliminary," by Prof. Ewart and Sir J. Ramsay Gibson-Maitland, gives the results of an important item in last year's work. The Act already referred to having empowered the Scotch Fishery Board to frame by-laws for the better regulation of sea-fishing, and one such law having been framed, passed, and confirmed, it was necessary to make arrangements to discover, if possible, what influence the prohibition of trawling under the by-law would have in leading to

an increase of fish in the protected waters. At the outset it was evident that it would be necessary to make systematic observations on the various areas by trawling along the same lines, and as nearly as possible under the same conditions, as the ordinary steam trawlers; and further, that it would be equally necessary to obtain as far as possible a record of the fish captured day by day from the various grounds in the Firth of Forth, St. Andrews and Aberdeen Bays.

Representations having been made that a small steam-vessel properly fitted out was indispensable, and a sum for the buying and maintenance of such a vessel having been granted, the *Garland*, an iron fishing yacht, was purchased and duly equipped. She was provided with a steam winch, trawling gear, dredges, &c., and later it was found desirable to add a small bridge to admit of a better "look-out" being kept when at work during the night in the vicinity of small fishing-boats, often imperfectly protected by lights. The beam of the trawl provided is twenty-five feet in length, *i.e.* about half the length of those used by the ordinary steam trawlers. This size was selected partly to suit the weight of the ship, and partly to cause as little disturbance as possible to the fishing-grounds when under periodical inspection. Special forms were prepared to admit of a complete record being kept of the fish taken by the trawl, dredge, and tow-net, and of the temperature, state of the weather, &c. The *Garland* was supplied with charts, showing the extent and direction in which the trawl was to be carried in working over the various trawling stations, and with several books of reference, bottles, tanks, &c., for the preservation of spawn, young fish, crustacea, and other objects which required to be afterwards examined or identified. Recently a complete set of thermometers and other instruments for making physical observations have been provided, and the necessary instructions given for their use.

In the present Report it is pointed out that the Firth of Forth is well adapted either as a feeding-ground or a nursery for the most important of our food-fishes and also for shell-fish. As a matter of fact, there is not, it is stated, on the east coast of England or anywhere else on the coast of Scotland, a stretch of water with so many natural advantages from the fishermen's point of view as the Firth of Forth. The fresh water carries with it food for mussels and other shell-fish. The sea brings in food for herring and other round fish. The water varies considerably in depth and salinity, and the bottom at one part consists of sand or mud, at another of gravel or shingle, and at another of rocks, sometimes bare, sometimes covered with sea-weed, and the temperature throughout the year is fairly constant, there never being great heat in summer or very great cold in winter. The physical conditions of St. Andrews Bay are entirely unlike those of the Forth, and this being the case the fauna may naturally be expected to differ considerably. There has not been time to prepare a complete account of the fauna of St. Andrews Bay during the different months of the year, but it is hoped that with the help of Prof. McIntosh a first list will be ready for the next Report. It is, however, known already that the rocky ground on the south shore is rich in mollusks, crustacea, marine worms, cœlenterates, &c.; and that starfish and other echinoderms, edible, swimming, and hermit crabs and other crustacea are scattered in abundance over the sandy bottom of the bay, and especially that mussels abound near the mouth of the Eden. Further, swimming or pelagic forms (including at certain seasons of the year schools of young fish, crustacea, and mollusks) teem in the surface and deeper waters. As is to be expected from the nature of the bottom, flat fish far out-number round fish all over the bay. The flat fish are chiefly represented by several kinds of dabs, by plaice, flounders, skate, and brill, and at times turbot; and in addition the bay is visited by haddock, whiting, cod, and other round fish. Aberdeen Bay corresponds in some respects with St. Andrews Bay, but the closed area includes not the bay proper so much as a narrow portion of the territorial waters (some eighteen miles in length) which extends from Girdle Ness to the Cruden Scars. This area, very narrow at certain points, never reaches a width of three miles. The Dee, Don, and Ythan flow into the bay, but the fresh water flows over the salt without mingling with it as in the Forth to form a true estuary. The bottom consists chiefly of sand, but towards the north and south sand gives place to rock. The fauna resembles that found at St. Andrews, but although flat fish are relatively plentiful, whiting are far more abundant. It is to be observed that, in comparing the prominent features of the three districts investigated, the Firth of Forth is characterized by an abundance of haddocks, St. Andrews Bay by the predominance of flat fish, and Aberdeen Bay by the large number of gurnards and whitings. As regards the practical working of the by-law, it is only necessary to add that although only a year has elapsed since it was passed, providing for a limited form of protection for the waters referred to, there are already some signs of improvement both in the number and size of the less migratory flat fish, and in the number of young round fish which visit the territorial waters for long or short periods. The fishermen of the Forth and St. Andrews Bay state they are already obtaining better takes of flat fish, and that they believe in a few years the in-shore grounds will have recovered to a considerable extent their former richness.

Prof. Ewart gives an interesting paper on "The Artificial Hatching and Rearing of Sea Fish." The publication last year of "The History of Howietoun" (Sir J. Ramsay Gibson-Maitland) marks an epoch in the history of fish-culture. It affords proof that the Salmonidæ at least can be bred and reared in confinement as successfully as any of the smaller domestic animals, and that fish-culture, notwithstanding all the reverses it has suffered through the misplaced zeal and energy of its many would-be advocates, has a great future before it, not only in re-stocking our own rivers and lakes, but also in peopling the waters of all countries where the conditions are favourable to the development and growth of the Salmonidæ and other valuable food-fishes. Fish-culture at Howietoun has been reduced to a science. Every step in the process, from the impregnation of the eggs to the rearing of the mature fish, has been thoroughly mastered and systematized. So careful have the observations been from first to last, that it is now possible to produce, within certain limits, considerable modifications in the time at which the eggs mature and hatch, and in the rate of growth of both the fry and the older fish; and, further, many hybrids have been bred, the genealogy of which is not a little hard without the aid of an ancestral tree to fully comprehend.

The reasons for putting such knowledge acquired to a practical application are that the demand for salmon is greater than formerly, and the nature of the spawning-grounds has been altered. Nature provides for all natural losses, but she does not, and cannot be expected to cope with those created by the necessities of civilization. It is for science to step in and help to solve the problem of supply and demand.

Unlike the higher animals, fish are not protected in the early stages, and the food-fishes even less than others. A very limited acquaintance with the life-history of sea-fish enables one to readily understand that, though the culture of salmon and trout may be highly advantageous, and often all but imperative, it does not follow that this is the case with the herring and cod and their allies. The most sanguine pisciculturist would scarce dare propose to increase the number of the more migratory fish that live in the open sea. It has been suggested that, by hatching

fish in-shore, local races might be formed; but this is taking for granted that during the process of incubation the fish are brought under some remarkable spell which arrests their strongly inherited instincts, and leads them to settle down for life in the vicinity of their birthplace, instead of roaming about to see the world like their free-born cousins. It seems, therefore, too much to expect cod and haddock and other wanderers to remain always about our doors because they happened to see the light under artificial instead of natural conditions. But though fish-hatching may not be able to influence much, if at all, the number of fish in the open sea, and though it may not be able to establish local races or shoals, it may still be of great service. In the first place, it may be the means of introducing fish, which have the migratory instinct fairly well developed, into waters where they practically did not previously exist. For example, by instituting hatcheries in the upper reaches of some of the long fjords in Norway, a large school of haddocks or other round fish might be readily created which might find all the conditions necessary to their existence without wandering into the open sea; and, in fact, the same results might follow the hatching on a large scale of round fish in some of our own firths and bays. Again, as in America, it might be possible to produce shoals of fish, such as the shad, which, by wandering along the coast or living in the estuaries, would be the means of attracting large and more valuable forms to the in-shore grounds; fish, in fact, which would act the part of the herring, but be a more constant source of attraction—remaining in the firths for several months at a time. Lastly, fish-culture may have a great future before it in hatching flat fish, which have the double advantage of being extremely valuable, while they are often very limited in their migrations. The artificial hatching of sea-fish has not yet had time to obtain a firm footing; for the first trustworthy experiments made were those of the German Commissioners (Meyer, Möbius, and others), who hatched numerous herring in 1874 in the Bay of Kiel. As is well known, Norway has a Society for Promoting the Norwegian Fisheries, with branches at the principal fishing centres. In 1882 an experimental station under Captain G. M. Dannevig was started at Flödevig, near Arendal, where millions of sea-fish have been hatched, and a number of cod and herring reared in a pond near the hatching station. The question of hatching sea-fish is under consideration at the present moment at Grimsby. It is proposed to found a hatchery at Cleethorpes to propagate round and flat fish, with a view of replenishing the exhausted in-shore waters of the North Sea. Even should this experiment prove unsuccessful, it will be of importance in furnishing and spreading the technical education and information so much required among those engaged in the fishing industry.

To successfully hatch sea-fish in large numbers, the first and last requisite is an abundant supply of pure sea-water. This necessitates a small sea-pond and a number of large tanks, from which a constant supply of pure filtered water can be readily obtained. In addition to having at command an abundant supply of sea-water, it is, of course, necessary to have the hatching-station in the vicinity of some rich fishing-ground, where plenty ripe fish may be obtained when wanted.

Given plenty pure sea-water and a number of ripe fish, the next desideratum is a hatching apparatus, the form of which must depend on the nature of the eggs to be manipulated. While herring eggs are heavy, and not only fall to the bottom, but adhere to whatever they touch, the eggs of most of the food-fishes are non-adhesive and lighter than sea-water, and hence they float at or near the surface. Prof. Ewart describes and figures a promisingly practical hatching jar for adhesive eggs lately designed and used by himself, also the apparatus used at Arendal for floating eggs, the most successful hitherto devised. With such apparatus it would be possible, at a very small outlay, to hatch millions of floating food-fish eggs, and thus to restore and maintain the original productiveness of the in-shore fisheries. The conclusion is that we ought to establish hatching stations at one or more centres. One might be for round fish, the other for lobsters and other shell fish. The Firth of Forth and the Cromarty Firth seem admirably adapted for the purpose, one great point being that minute pelagic forms, such as the young fry feed on, are remarkably abundant in both. A hatching station could be provided for about £1000, and it is hoped the Board may soon obtain a vote for the purpose. The hatching operations at Flödevig, of the report of which Prof. Ewart gives an interesting abstract, shows that many important practical questions have been settled, and the conclusions reached at Howietoun and elsewhere as to the influence of extreme temperatures, sudden changes in the surroundings, and also on the eggs and young spawn on full-grown fish, have been well confirmed.

Mr. Duncan Matthews gives (Part I.) a long paper, excellently done, on "The Structure of the Herring and other Clupeoids," with a series of capital plates; also Part II. of the "Report as to variety among the Herrings of the Scotch Coast"; notes on "The Food of the Whiting," and on the "Ova, Fry, and Nest of the Ballan Wrasse." Mr. R. D. Clarkson's paper "On the Nutritive Value and Relative Digestibility of White Fish" is as interesting from the dietetic point of view as Mr. C. E Fryer's suggestions for "The Preparation of Sprats and other Fish as Sardines" is from the economic. Prof. McIntosh reports on the work done last year at the St. Andrews Marine Laboratory. The other scientific investigations include notes on "The Food of Young Gadidæ," and on "The Spawning of the Pike," by Mr. George Brook; on "Entomostraca," by Mr. G. S. Brady; a paper on the "Development of the Common Mussel," by Mr. John Wilson; one on "The Physical Conditions of the Water of the Firth of Forth," by Dr. H. R. Mill; and a "Further Report on the Examinations of River-waters for Micro-organisms," by Prof. Greenfield and Mr. John Gibson. There are a number of tables and plates which add greatly to the interest and usefulness of the work.

PROFESSOR A. WEISMANN'S THEORY OF POLAR BODIES.

ONE of the most noticeable features at the recent meeting of the British Association at Manchester was the manner in which naturalists of all nationalities agreed to do honour to Prof. Weismann, who has contributed to theoretic biology in the last few years with as lavish a hand as that with which he formerly enriched the practical side of the science through detailed observation and far-reaching induction.

Of his later speculations upon the significance of obscure reproductive phenomena, the first[1] was abridged by Prof. H. N. Moseley (NATURE, vol. xxxiii. p. 154); while perhaps the most important contribution to biological science at the Manchester meeting was an abstract of the newer pamphlet[2] recently reprinted in this journal (vol. xxxvi. p. 607). The necessary limits of such an abstract precluded any account of the observations which appeared to support Prof. Weismann's views, as also of the details of the process by which, as he supposes, the plasmata are removed in the polar bodies. As neither the original pamphlet nor the still later account of his observations upon parthenogenetic eggs are generally accessible, it has been suggested that some additional points, in expansion of the abstract, should be given in these columns.

1 "Die Continuität des Keimplasma's," Jena, 1885, 122 pages.
2 "Die Zahl der Richtungskörper," Jena, 1887, 75 pages.

Certain recent observations on the maturation of the ovum are of great interest in this connection, as illustrating the possible mechanism by which ovogenous plasma in the extrusion of the first polar body, and a number of ancestral plasmata in that of the second, are removed from the nucleus of the ovum; the former process being designed to *equalize* in bulk the ovogenous and germinal plasmata contained in the nucleus (*Aequationstheilung*), the latter to *reduce* the total number of ancestral plasmata present by a half (*Reduktions-theilung*).

For this reduction in number of the ancestral plasmata there must be a second and special form of karyokinesis not as yet generally recognized. If any value be attached to the fact, first observed by Flemming,[1] that in normal karyokinesis the nuclear loops are split longitudinally, one of the resultant halves passing to each daughter-nucleus, then the two nuclei produced by such division must be precisely alike, not only quantitatively, but qualitatively. For Prof. Weismann's view, however, there must exist "a type of karyokinesis in which the primary equatorial loops are not split up, but separated into two groups, each of which groups forms one of the two daughter-nuclei." E. Van Beneden[2] has already shown that in the formation of the polar body of *Ascaris megalocephala* the nuclear division differs from the usual type of karyokinesis in that the plane of division is at right angles to the normal; and Carnoy[3] has more recently essentially confirmed the observation, and has further added that, of the eight nuclear loops which are to be found in the equator of the spindle, four are removed in the extrusion of the first polar body, and two of the remaining four with the second. Were it certain that each of the eight loops consisted of ancestral plasma, it would be necessary to regard the first division of the nucleus as a process of reduction, not of equalization; but this is not to be accepted, mainly because the extrusion of the first polar body is to be found also in parthenogenetic ova. With more probability the first polar body of the ovum of *Ascaris* is to be regarded as removing ovogenous plasma, since we know, through the observations of Flemming and Carnoy, that under certain conditions secondary splitting and consequent numerical duplication of the nuclear loops may occur. This shows, in Prof. Weismann's view, that there exist nuclei in which the same ancestral plasmata may be present in different loops. Such "identical loops," however, are not necessarily at the same ontogenetic grade; and this is probably the case here, as the four loops of the first polar body must be regarded as ovogenous plasma, the other four as germinal plasma. This would be practically proved if it could be shown that the eight loops were produced by longitudinal splitting of four primary loops, since such splitting is the means of separating plasmata of different ontogenetic grade from one another, without diminution of the number of ancestral plasmata.

With regard to the male cell, the facts at our disposal are too few to enable us to speak with such confidence as is the case with the ovum, but whether the theory of Pangenesis, or of the Continuity of Germ-plasma, be proved correct, a process of reduction of ancestral plasm similar to that occurring to the ovum must also take place in the maturation of the sperm cell, though probably after a different manner. The ancestral plasmata of the ovum undergo reduction only at the termination of ovarial maturation. Supposing, however, that reduction affected the first ovicell of an organism only, and that the rest were produced from this by normal division, then there would be practically but two kinds of ova in the ripe ovary, coresponding to the two halves of the original ovicell, and but two kinds of individuals produced from them, the members of each kind resembling each other as closely as twins. On the

[1] *Arch. Mikr. Anat.* xvi., and elsewhere.
[2] *Arch. Biol.* iv.
[3] *La Cellule*, 1886.

other hand, the later the period of germ-cell-formation at which the reduction is effected, the more will the ova differ in composition from one another, and the greater scope is afforded for variation among the resultant individuals. Finally, if reduction be deferred till the ova be mature, the variation insured among the progeny is as great as it is possible to achieve. The production of such maximum variation is the probable explanation of the fact that the second polar body is not extruded till the *end* of maturation. With the sperm-cells, however, the conditions of number and size are different from those obtaining in the ova. Though it is quite conceivable that the process of reduction may be deferred till the completion of sperm-cell formation (both of the fission-products probably remaining as sperm-cells), still the other possibility must also be considered—namely, that it may take place at an earlier date in the formation of the sperm, since the opportunity for extreme variation, however necessary in the case of ova of which a considerable proportion are fertilized, is far less requisite among sperm-cells, of which perhaps one in a hundred thousand or a million may be actually effective. The question can only be settled when we know which of the forms of nuclear division it is that effects the reduction of ancestral plasmata; in the meantime there is evidence to show that different types of fission are found at different stages of sperm-cell formation. Van Beneden and Julin[1] have shown that direct and karyokinetic division alternate in the spermatogenesis of *Ascaris megalocephala;* and the observations of Carnoy[2] and Plattner[3] on Arthropoda further point to the occurrence, at certain stages, of that less-known type of karyokinesis which, according to Prof. Weismann, is cha[illegible] the process of reduction. The "*Nebenkern*," described by La Valette St. George as occurring at the penultimate stage of spermatogenesis, is probably comparable to the first polar body extruded by the ovum.

As is now generally known, Prof. Weismann has succeeded in demonstrating that one, and only one, polar body is extruded from the parthenogenetic ovum; but the memoir[4] dealing with the details is but recently published, and is in a periodical inaccessible to most readers. His observations cover the following species:—

CLADOCERA.
Polyphemus oculus.
Leptodora hyalina.
Bythotrephes longimamus.
Moina rectirostris.
Moina paradoxa.
Daphnia longispina.
Daphnella brachyura.
Sida crystallina.

OSTRACODA.
Cypris reptans.
Cypris fusca.

ROTIFERA.
Callidina bidens.
Conochilus volvox.

The process in the Cladocera is as follows. The nucleus of the ovum approaches the periphery, and becomes gradually fainter till it is no longer recognizable except by the help of reagents. A normal nuclear spindle is then formed, and the polar body cut off with the resultant half-nucleus. After extrusion, the polar body may in some instances not only segment, and one of the resultant cells again segment, but, in the case at least of *Moina*, it appears that it secretes that part of the egg-shell which immediately overlies it, so that its true cell-nature is indisputable.

With regard to the Rotifera, a group in which its occurrence has been denied, a true parthenogenesis is proved by the following observation. A female of *Callidina* with two uterine embryos was isolated on a slide; after

[1] *Bull. Acad. Belg.* (3) vii. 312.
[2] *La Cellule*, 1885.

the lapse of a day was born a young one, which possessed in its uterus an ovum already in segmentation. From this ovum two days later was produced a third female, while a second ovum in the uterus of the mother was also already commencing to segment. Whether *all* the "summer" (parthenogenetic) eggs develop into females or not, has yet to be proved. Here also it was shown that one polar body was extruded.

The second part of the memoir sums up the literature relating to the subject, with the result that the extrusion of two primary polar bodies from fertilized ova has been demonstrated in sixty-six cases, that of one only from parthenogenetic ova in fourteen cases; while none of the few observers who describe the extrusion of one polar body only from a fertilized ovum, have endeavoured to show that a second one may not have been present, at an ontogenetic period other than that which they describe.

G. HERBERT FOWLER.

SIEMENS'S GAS-BURNERS.

OWING to the very high temperature of ignition of gas, the only way in which it can be successfully used with the greatest economy is by the application of regenerators. This was proved practically by the late Sir William Siemens in carrying out his own and his brother's invention of the regenerative gas-furnace. For more than eight years now Mr. Frederick Siemens has devoted a portion of his attention to the domestic applications of gas, and he has quite recently opened a depot in the Horseferry Road for the sale of his gas-lamps. Here, on Tuesday afternoon, he entertained several gentlemen interested in gas illumination, and tested photometrically some of the burners we propose to describe and illustrate.

It is well known that the light intensity of a flame increases with its temperature in a higher ratio than the arithmetical, although the actual ratio has not been absolutely determined. It is, moreover, known that the more the energy of flame is transformed into radiant light and heat the less is the amount carried away in the products of combustion. But the difficulty is to take advantage of these laws in practice, and to combine high temperature with durability, and the use of regenerators with simplicity of arrangement and elegance of appearance in the lamp.

After the Smoke Abatement Exhibition, at which Mr. Frederick Siemens's regenerative gas-lamps were for the first time exhibited in this country, a great outcry was raised on account of their unsightliness. The economy

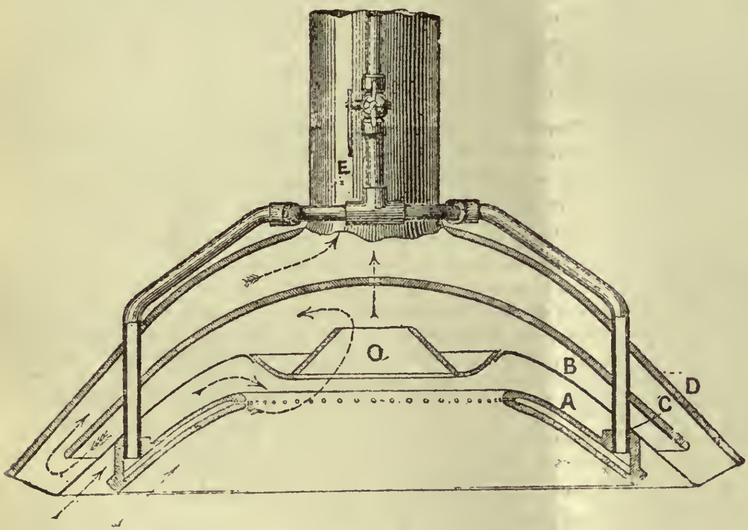

FIG. 1.

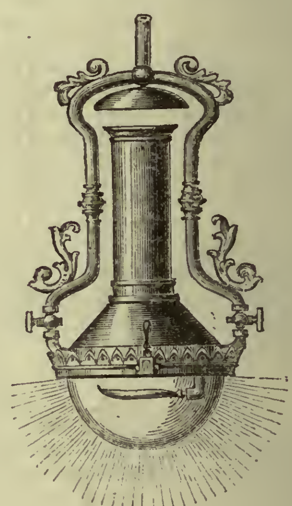

FIG. 2.

of the light and its intensity were in vain dwelt upon: the British public were not inclined to entertain the new lamps, and a comparatively small business was done in them. Besides this, it was discovered by degrees that when impure gas was employed the gas passages became blocked with a sulphurous deposit, so that, in order to maintain their high efficiency when in constant use, these passages had from time to time to be cleared. Mr. Siemens set to work to overcome both these defects, and the lamps he has now produced lend themselves to artistic ornamentation, and have no passages to offer obstructions to gas of ordinary quality.

The lamp we propose to describe in the first instance is the one known as the open-flame sunlight pattern. It is designed for use in positions where the ordinary sunlight lamp is employed, such as public halls, concert, dining, and billiard rooms, banks, and theatres. The flame in this lamp is extremely delicate and elegant in appearance, having the form of an inverted cone of light, apparently unsupported. The annexed drawing illustrates the construction of this lamp. Four hoods made of suitable material are arranged one above the other so as to form passages through which the products of combustion are removed, their waste heat being utilized to heat the air supplied to the flame. The jets of flame issue in a ring from the lowest hood; the products of combustion, passing through the aperture O, are drawn downwards through the annular space B, and then upwards through C to the chimney E. The hood between the passages A and B is intensely heated by the products of combustion descending on its upper surface; and the air which travels through the annular space A, on its way to supply the gas-jets, takes up the heat from the hood, the flame being thus supplied with heated air, as well as burning in an intensely hot atmosphere. The lamp we were shown consumes 24 cubic feet of gas per hour, and gives, with ordinary London gas, a light equal to 180 sperm candles, or 7·5 candles per cubic foot of gas, which is more than twice the light obtainable from the same amount of gas burnt in ordinary burners. This lamp was set up with a ventilator, but was much too brilliant for use in the room in which it was exhibited, the ceiling being only about 12 feet above the floor, whereas it should be placed at an elevation of 30 feet or more, when it would not only serve for illuminating-purposes, but also for those of heating.

The Siemens regenerative flat-flame burner, as will be noticed from the accompanying illustration, is a lamp of a quite different character from the one just described, burning as it does within an inclosing glass, the previous lamp being quite open to the air. The lamps exhibited consumed from 7 to 8 feet of gas each per hour, and are of various ornamental forms. It consists simply of an ordinary bat's-wing burner supplied with hot air through perforated plates, which are heated by the waste heat from the products of combustion, and by radiant heat communicated to the perforated plates. The advantages of this form of lamp are those of construction, application, and economy. The principal parts of the regenerator consist of simple castings, whilst the only wearing part is the tip or burner, which is, as already stated, of the ordinary kind, and may be easily replaced at trifling cost. It can be fitted to the ceiling of a room like any other gas-lamp, or may be connected up to a chimney, so that the products of combustion may be withdrawn from the apartment. There is a provision for lighting this lamp without removing the glass globe, the glass being sufficiently far removed from the flame not to receive any

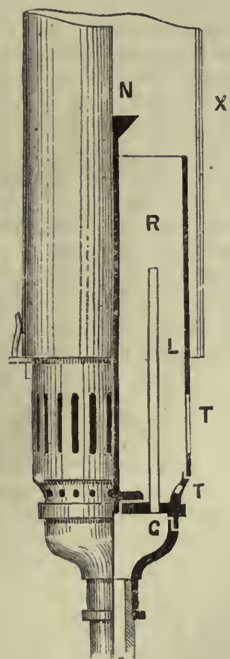

Fig. 3.

deposit upon its surface. With a consumption of 7·2 cubic feet of gas per hour, this lamp has been found to give without reflector a light equal to 72 sperm candles, or 10 candles per cubic foot, being more than three times the light produced by ordinary gas-burners, whilst if three flames are inclosed in the same lamp the efficiency obtained is still higher.

A third form of burner is Siemens's improved argand. This is not a regenerative gas-burner properly so called, and hence the economy is not so great as in either of the burners previously described. Instead of utilizing the waste heat of the products of combustion, in this burner the heat of the lower or non-luminous portion of the flame is applied for the purpose of heating up the air which is supplied to the burner. The sketch shows the arrangement in half-section. It consists of gas-chamber, G, and tubes, R, from which the gas issues and is burnt; a metal stem, N, rises a certain height above the top of the gas-tubes, serving the double purpose of improving the form of the flame and conducting a certain amount of heat down to assist in heating the air supplied to the burner. The air enters through the slots T, in the lower portion of the cylindrical case L, which surrounds it, a hot chamber being thus formed, from which the heated air passes to the flame. A glass chimney, X, incloses the flame as in the ordinary argand burner.

By means of this lamp an intense white light is produced with some economy of gas, the light produced with 6 cubic feet of gas being 26 candles, or 4·33 candles per cubic foot per hour, as compared with 3·2 in the ordinary form of argand burner. When an opal glass shade or reflector is used, throwing down a portion of the light, this burner gives a light of 6·33 candles per cubic foot. Its applications are various, but it is mainly applied for reading and desk purposes.

Mr. Siemens, in reply to a vote of thanks, said that the only economical way of burning gas was with the application of regenerators. This had already been proved by both the late Sir William Siemens and Mr. Frederick Siemens as regards furnaces for industrial purposes, and it is now being exemplified by Mr. Frederick Siemens in the domestic applications of gas.

NOTES.

The University of Cambridge has sustained a severe loss by the death of Mr. Coutts Trotter. He died on Sunday morning last. Next week we shall give some account of his services to his University and to science.

The United States Chief Signal Office has suppressed both its mountain stations, Pike's Peak and Mount Washington. The latter was suppressed at Michaelmas. The grounds alleged are—the reduction of the grant by Congress, which has been very serious, and, further, inability to use the reports in forecasting.

The Chief Signal Officer (Washington) has issued a circular, dated November 10 last, stating that, in view of the large number of letters he has received deprecating the discontinuance on January 1, 1888, of the International Meteorological Observations (see Nature, vol. xxxvi. p. 545), he has decided to continue to receive such observations, made at noon, Greenwich time, after that date. He does not promise to publish them as regularly as heretofore, but he will do what he can to give observers some return for their labours in the interests of the science of meteorology.

The *Annalen der Hydrographie und Maritimen Meteorologie* for November contains the first part of the explanatory text of the daily synoptic charts of the North Atlantic Ocean for the winter quarter of 1883-84, together with charts showing the positions of the principal barometric maxima and maxima (see Nature, vol. xxxvi. p. 159). The depressions of January 22-31 are of especial interest, as they include the lowest barometrical reading ever recorded in Europe, viz. 27·332 inches at Ochtertyre, near Crieff, N.B., on January 26, 1884. The readings nearest to this are 27·33 inches, about 6° further south in the Atlantic, on February 5, 1870, and even 27·245 inches in Iceland on February 4, 1824. A still lower reading has lately been quoted for False Point (Nature, November 17, p. 68). The storm of January 26-27 was also remarkable for the rapid fall before, and the rapid rise after, the minimum pressure.

The Monthly Weather Charts of the Bay of Bengal and adjacent sea north of the equator, recently published by the Meteorological Department of India, very clearly illustrate the distribution of pressure, wind, and currents, as well as the changes of the monsoons, in those parts. The charts have been prepared from data for the years 1855-78, and supplied by the Meteorological Council, at the expense of the Indian Office. Each chart is accompanied by explanatory text.

LAST Saturday there was a severe earthquake in Calabria. Two shocks were felt: one at 5 o'clock in the morning, the other two hours later. Both shocks were felt all over the province of Cosenza, but the second was by far the most violent. All the signalmen's huts on the railway near Sibari were destroyed for a distance of 8 kilometres. The station of Lattarico was also destroyed. At Paola the barracks and the Prefecture and Communal buildings were damaged; at Rogliano and Gravina several houses fell, and all the others were seriously shaken; and at San Marco part of the monastery fell. The results were most disastrous at Bisignano, the greater part of which was destroyed. More than twenty persons were killed, and about seventy injured. The parish priest of Bisignano, after having made his escape from the church, re-entered it, when the building fell in, and he was killed. The results at Bisignano would have been even more terrible, had not most of the inhabitants, alarmed by the first shock, fled from their houses. It is said that 900 houses are in ruins.

A CORRESPONDENT writes to us from Blackburn:—"A shock of earthquake occurred at Chorley, Lancashire, on December 1, at about 10 minutes to 7 o'clock a.m. It was also felt over a wide area. At Blackburn, two distinct vibrations were felt. The direction of the disturbance appeared to be from south-west to north-east."

ON November 5, at 7.16 p.m., a severe shock of earthquake was felt at Bodö, on the north-west coast of Norway. Houses shook, and several objects on walls fell down. There was only one shock, and it lasted about half a second.

ON the evening of November 21, at 5.18 p.m., a magnificent meteor was observed in the neighbourhood of Stavanger, on the west coast of Norway. It first appeared in the western sky, and, having described a semicircle, disappeared below the horizon. Its size was that of a child's head, and its light a brilliant white. The weather was fine and starry at the time.

MR. JOHN AITKEN has contributed to the Proceedings of the Royal Society of Edinburgh an interesting note on the formation of hoar-frost. Experiments were made with a sheet of glass exposed horizontally near the ground. During the deposition of dew the windward edges were generally dry, because the air has to travel over the cold plate before its temperature is reduced to the dew-point; but, when hoar-frost is deposited, the windward edges of the plate have the heaviest deposit. In this case the air seems to act as if it were supersaturated. Although this is impossible in ordinary conditions, the author shows that, if we have a water suface and an ice one at the same temperature, the vapour will tend to pass from the water to the ice, because the vapour-pressure of water is the higher; and he concludes that something like this takes place when hoar-frost is forming, the air which is saturated to a water surface being supersaturated to an ice one.

DR. FRIDTJOF NANSEN, of the Bergen Museum, has announced his intention of attempting to cross the interior of Greenland next summer on *Ski*, viz. the snow-runners found so advantageous during the last Nordenskiöld expedition across that continent. It may be remembered what extraordinary progress the Lapps made at that time on these Scandinavian means of locomotion across snow-fields. Dr. Nansen, who has on a former occasion visited the inland ice in Greenland, has placed his plan before Baron Nordenskiöld, who fully believes in its realization, and is giving Dr. Nansen every assistance. The explorer purposes crossing from the east to the west coast, the reverse of Baron Nordenskiöld's attempt.

AN important paper by Prof. Lothar Meyer, upon the subject of "oxygen carriers," will be found in the current number of the *Berichte*. It embodies the results of a systematic series of experiments in which currents of oxygen and sulphur dioxide gases were simultaneously passed for some hours through solutions of certain salts of known strength contained in flasks heated upon the water-bath. At the end of each experiment the sulphur dioxide remaining in solution was expelled by a current of carbon dioxide, and finally a determination was made of the amount of sulphuric acid formed by oxidation of the sulphur dioxide. The results show that the salts of certain metals exert a most remarkable action in causing the union of oxygen with sulphur dioxide. The most active of all is manganous sulphate, $MnSO_4 . 5H_2O$, 2·4 grammes of which, dissolved in 200 c.c. of water, caused the formation of no less than six times as much sulphuric acid as that originally contained in the salt; that is, for every molecule of the sulphate employed, five molecules of free acid were synthesized. Manganese chloride under like circumstances was also found to act as an energetic oxygen carrier, one molecule of $MnCl_2 . 4H_2O$ causing the formation of 4·3 molecules of free sulphuric acid. Copper salts were next experimented upon, and a 3 per cent. solution of the sulphate, $CuSO_4 . 5H_2O$, was found to be most effective, one molecule causing the production of about a molecule of the acid. Both cuprous and cupric chlorides, the former in spite of its insolubility, act even more energetically than the sulphate, while the oxide hydrate, and, metal itself also work in a lesser degree. In a similar manner salts of iron, cobalt, nickel, zinc, cadmium, and magnesium were found capable of causing the oxidation of sulphurous acid, while salts of thallium and potassium merely acted like pure water, being absolutely powerless in this respect. These remarkable results are due, in the opinion of Prof. Meyer, to alternate oxidations and reductions, and this is certainly very strongly supported by the fact that those metals act most powerfully which readily pass from one stage of oxidation to another. As zinc, cadmium, and magnesium are also found to act in this manner, it is presumed that these metals have also an inclination to form sub-salts which have never yet been prepared.

SOME days ago a peasant ploughing at Tjöring, in Denmark, unearthed a handsome armlet of pure gold weighing 12 ounces, which, according to the Director of the Museum of Antiquities in Copenhagen, dates from the second or third century A.D. There was formerly a barrow in the field where the armlet was found, and flint implements, broken pottery containing decayed bones, &c., have frequently been brought to light; but all traces of the barrow have now disappeared through ploughing.

IT is reported from India that Mr. Rea, of the Madras Archæological Survey, has recently excavated some ancient burial-places at Dadampatti, Paravai, and other places in the Presidency, and investigated the cromlechs near Kodaikanaul. He has obtained a considerable collection of ancient pottery, and in some of the tombs found a large number of bones and a complete human skull. The latter had been filled up and inclosed in soft clay, so that its contour and characteristics are perfectly preserved. Mr. Rea also brought away a small specimen of a pyriform tomb.

LAST Thursday, Sir John Lubbock read a paper before the Linnean Society, in continuation of his previous memoirs, on "The Habits of Ants, Bees, and Wasps." He said it was generally stated that our English slave-making ant (*Formica sanguinea*), far from being entirely dependent on slaves, as was the case with *Polyergus rufescens*, the slave-making ant *par excellence*, was really able to live alone, and that the slaves were only, so to say, a luxury. Some of his observations appeared to throw doubt on this. In one of his nests the ants were prevented from making any fresh capture of slaves. Under these circumstances, the number of slaves gradually diminished, and at length the last died. At that time there were some fifty of the mistresses still remaining. These, however, rapidly died

off, until at the end of June 1886 there were only six remaining. He then placed near the door of the nest some pupæ of *Formica fusca*, the slave ant. These were at once carried in and soon came to maturity. The mortality among the mistresses at once ceased, and from that day to this only two more have died. This seems to show that the slaves perform some indispensable function in the nest, though what that is still remains to be discovered. As regards the longevity of ants, he said that the old queen ant, which had more than once been mentioned to the Society, was still alive. She must now be fourteen years old, and still laid fertile eggs, to the important physiological bearing of which fact he called special attention. He discussed the observations and remarks of Graber as regards the senses of ants, with special reference to their sensibility towards the ultra-violet rays, and referred to the observations of Forel, which confirmed those he had previously laid before the Society. Prof. Graber had also questioned some experiments with reference to smell. He, however, maintained the accuracy of his observations, and pointed out that Graber had overlooked some of the precautions which he had taken; his experiments seemed to leave no doubt as to the existence of a delicate sense of smell among ants. As regards the recognition of friends, he repeated some previous experiments with the same results. He took some pupæ from one of his nests (A) and placed these under charge of some ants from another nest (B) of the same speciés. After they had come to maturity, he placed some in nest A and some in nest B. Those placed in their own nest were received amicably, those in the nests of their nurses were attacked and driven out. This showed that the recognition is not by the means of a sign or password, for in that case they would have been recognized in nest B and not in nest A. Dr. Warsmann had confirmed his observations in opposition to the statement of Lespis, that white ants are enemies to those of another nest, even belonging to the same species; the domestic animals, on the other hand, can be transferred from one nest to another, and will be amicably received. In conclusion, he discussed the respective functions of the eyes and ocelli, and referred to several other observations on various interesting points in the economy of the Social Hymenoptera.

In an interesting paper read the other day before the National Academy of Sciences, New York, Prof. W. P. Trowbridge gave an account of a discovery which had lately been made by his son. This discovery is that birds of prey and some others have the power to lock securely together those parts of the wing holding the extended feathers, and corresponding to the fingers of the human hand. The action of the air on the wing in this condition extends the elbow, which is prevented from opening too far by a cartilage, and the wings may keep this position for an indefinite length of time, with no muscular action whatever on the part of the bird. While resting in this way, the bird cannot rise in a still atmosphere; but, if there be a horizontal current, it may allow itself to be carried along by it, with a slight tendency downward, and so gain a momentum by which, with a slight change of direction, it may rise to some extent, still without muscular action of the wings. Prof. Trowbridge also believed it quite possible for a bird to sleep on the wing. In discussing this paper, Prof. J. S. Newberry said that he had once shot a bird which came slowly to the ground as if still flying, but reached it dead. He believed that it had died high in the air; but he had never been able to account for the manner of its descent till now, when he found an explanation in the statement of Prof. Trowbridge.

The cultivation of oysters in France appears to have greatly increased of late. Thus, while in 1885 the number exported was 30,000,000, 35,000,000 have been exported in the first eight months of 1887 (twice as much as in the corresponding part of 1886), and the total for the year will probably be about 52,000,000. At the same time the importation into France from Portugal has been declining. Thus, from 154,647 kilogrammes in 1883, it had fallen to 1500 kilogrammes in 1885, and no figures are forthcoming for the first eight months of 1887.

In his Report for 1886–87, presented to the Parliament of Tasmania, Mr. Saville-Kent speaks of the oyster-fisheries on the Tasmanian coast-line. The results obtained during the past year, from the series of Government oyster-reserves established in accordance with Mr. Saville-Kent's recommendations, seem to him to justify the opinion that, with an extension of the same system, conducted on scientific principles, the produce of these reserves, combined with that raised on the private beds, will be sufficient within the course of a few years to establish once more a lucrative oyster trade in the colony. At all of the several reserves there has been an abundant fall of spat, but more especially in those of the Spring Bay district. This locality, Mr. Saville-Kent anticipates, will, as in former years, become the chief station of the Tasmanian oyster-fishery. The number of breeding-oysters at present laid down upon the various Government reserves may be reckoned at about 150,000; to these may be added, as the produce of the past year's spatting season, at least an equal number of young brood. A further supply of 100,000 adult stock, for placing on the additional reserves projected or in course of construction, will be obtained from the natural beds during the current year.

Mr. Harry Page Woodward (eldest son of Dr. Henry Woodward, F.R.S.), who had served for more than three years, under Mr. H. Y. Lyell Brown, as Assistant Government Geologist in South Australia, has, by the advice and upon the recommendation of Dr. A. Geikie, F.R.S., Director-General of the Geological Survey of Great Britain, been appointed by the Secretary of State for the Colonies to the post of Government Geologist for Western Australia. Mr. Woodward sailed for King George's Sound in the P. and O. steam-ship *Shannon* on the 2nd inst.

A peculiar phenomenon is being noticed in the large lakes near the village of Mazuren (near Gumbinnen, Prussia). The level of the water is continually decreasing; during the last ten years it has fallen 1 metre annually, so that many of the islands in the lakes have now become peninsulas.

The People's Lectures, begun under the auspices of the London Society for the Extension of University Teaching, have attracted large audiences, and there is no reason to doubt that the success hitherto achieved will be maintained. Yesterday evening, Prof. H. G. Seeley, F.R.S., delivered, at the Great Assembly Hall, Mile End Road, the first of a course of three lectures on "Glimpses into Nature's Workshop." The special subject of this lecture was "Water, the Earth Leveller." The next two lectures of the course—"Ice, the Earth Engraver," and "Underground Heat, the Earth Moulder and Modeller"—will be delivered on December 14 and 21, at the Memorial Hall, London Street, Bethnal Green.

Another series of lectures at the Memorial Hall, London Street, Bethnal Green, is likely to be of good service. It is intended especially for working lads, and the lectures are called "Science Talks." Last Thursday, Dr. Gerard Smith delivered a lecture on "The Structure of Trees and Plants"; and this evening he will lecture again, taking as his subject "Microscopic Life in the Sea." On December 15, Mr. C. A. Newton will lecture on "The Wonders of the Heavens."

A Conference on Technical Education will be held at the Royal Victoria Hall, Waterloo Bridge Road, on Wednesday, the 14th inst. Sir Henry Doulton will take the chair. Two short papers—one by Dr. Fleming, of University College, the other

by Mr. Bochett, a working man—will be read; and it has been arranged that the reading of these papers shall be followed by a discussion. It is hoped that employers and employed will both be largely represented at the meeting. The Hon. Secretary will be glad to send tickets for the platform or for reserved seats to anyone who may apply for them.

IN the Report of the Newcastle Public Libraries Committee for 1886–87, it is stated that, at the annual stock-taking in June-July 1886, only three volumes were found to be unaccounted for. Only sixteen volumes have been lost since the opening of the Library in 1880. During the same period the issue of v olumes has reached a total of 1,538,445.

A NEW edition of the catalogue of books in the juvenile lending department connected with Newcastle Public Library has just been issued. A glance at the contents, as the compiler truly says, will show that in this juvenile department "a wonderful wealth of entertainment is placed at the command of the young people of Newcastle." No fewer than two thousand carefully selected volumes are at their disposal. During the seven years the Library has been open, the Committee has more than doubled the stock of books in this collection, and 215,092 volumes have been lent to children.

A VISITOR to the beaver colony at Amlid, some distance from Christiansand, in Norway, to which we referred some months ago, states that the colony has flourished considerably during the summer, and is now probably the largest in Norway. Sometimes as many as a dozen animals may be seen at a time in the water. The huts are built close to the shore, and have two stories, one above and one below the surface of the water. The walls are made of timber, laid as in a human dwelling, whilst the roof is covered with twigs and mud. All the aspen-trees in the vicinity have now been felled, and the animals have begun to attack the birches. Trees upwards of 18 inches in diameter at the root have been cut down. The animals appear to have most use for the branches, many stems stripped of the same lying about in the woods. The material required is dragged to the waterside along regular "log runs," su ch as wood-cutters leave in forests, and in some places roots crossing the same have been gnawed off, so as to make the run smooth. Shortly after an increase in the colony the new-comers begin to build a new house. Not one of the animals has as yet been killed, and visitors come from all parts for the purpose of watching their peculiar mode of living. It has been found that sentinels are posted, giving the alarm to the rest of the colony in case of danger. When such an alarm is given, all the animals leave their dwellings for the water.

READERS of Icelandic Sagas will remember that in the celebrated Njal's Saga there is a record of an attack on Njal's dwelling, Bergthorshval (named after his wife, Bergthora), and of its being burned, with the whole of Njal's kin. In order to demonstrate the historical accuracy of the Saga, a member of the Iceland Archæological Society some two years ago proposed to excavate the spot where Njal's dwelling was said to have stood. This was done last year, and resulted in the discovery, at a depth of some 6 feet, of a layer of ashes, remains of charred beams, &c. But this was not all. Below the ashes three lumps of some substance of a spongy nature, dirty-white in colour, were found; and Dr. Storch, Director of the Royal Agricultural Laboratory in Copenhagen, by whom these lumps have just been analyzed, pronounces them to be ancient curdled milk and cheese. Such milk, called *Skyr*, was much liked in Iceland in remote times, and was often solidified to a kind of cheese by the fluid matter being pressed out. Strangely enough, the Saga mentions the fact of women bringing *Skyr* to extinguish the fire. Dr. Storch, by slowly treating fresh *Skyr* to a temperature of a little more than 100° C., has thereby obtained a substance in every respect similar to that found in the supposed ruins of Njal's dwelling.

THE additions to the Zoological Society's Gardens during the past week include a Striped Hyæna (*Hyæna striata*) from North Africa, presented by Mr. Ernest Heydon Marquis; a Crested Porcupine (*Hystrix cristata*) from Suakim, presented by His Grace the Duke of Hamilton, K.T., F.Z.S.; two Common Squirrels (*Sciurus vulgaris*), British, presented by Mrs. Henry Alex. Hankey; a Horned Tragopan (*Ceriornis satyra* ♂) from the South-eastern Himalayas, presented by Mr. R. J. Lloyd Price; a Vinaceous Dove (*Turtur vinaceus*) from West Africa, presented by Mr. R. H. Mitford; three South African Scorpions (*Scorpio* ——) from South Africa, presented by Mr. W. K. Sibley; a Zebu (*Bos indicus*) from Africa, two Sandwich Island Geese (*Bernicla sandvicensis*) from the Sandwich Islands, deposited.

OUR ASTRONOMICAL COLUMN.

THE NEW ALGOL VARIABLES, Y CYGNI AND R CANIS MAJORIS.—Mr. Chandler has just published in *Gould's Astronomical Journal*, No. 163, his elements for these two interesting variables. In the case of Y Cygni, it will be recollected (see NATURE, vol. xxxv. pp. 307, 329) that before its period had been fully determined by observation, Mr. Chandler concluded, from the analogy of all the then known stars of the type, that it would prove to be about thirty-six hours. This is now found to be correct, the actual period being 1d. 11h. 56m. 48s. The ground upon which the inference was based was the circumstance that with the other stars of the type the shorter the period of the star the higher is the ratio which the time of oscillation bears to the entire period. The first exception to this rule is R Canis Majoris, the variable star discovered by Mr. Sawyer last March (see NATURE, vol. xxxvi. p. 376), the duration of the oscillation for this star being 5h. instead of 6h., as it should be on the same principle.

The following are the elements of the two stars:—

	Y Cygni.	R Canis Majoris.
Epoch	1886, Dec. 9, 11h. 14m. 30s.	1887, Mar. 26, 14h. 58m. 30s.

M. POTANIN'S JOURNEYS IN EAST TIBET AND EAST GOBI.

A CONDENSED report of the results obtained by the three years' journey of MM. Potanin, Skassy, and Berezovsky, in China, Amdo plateau of Tibet at the sources of the Hoang-ho, and East Gobi, has just appeared in the Russian *Izvestia* of the Geographical Society (iii. 1887.) Without repeating what has already been mentioned in his letters, M. Potanin gives in his paper a masterly sketch of the physical characteristics of the various regions explored by his expedition.

The route followed was from Peking, across the Utai-shan mountains which border the Peking depression in the west, and where the well-known Utai Buddhist monasteries are situated, to the city of Kuku-khoto. Thence south, across the Ordos region, to Lan-tcheu, capital of the Han-su province, and to San-tchuan on the middle Hoang-ho, where M. Potanin spent the winter of 1884–85, while M. Skassy wintered at the above city, and M. Berezovsky at Hoi-siang, on the Sy-tchuan frontier of the Han-su province. Thence the expedition proceeded south-east tp Min-tcheu on the Tao-he, and to Sun-pan. Lun-an-fu was the utmost point reached towards the south, and the expedition returned to Lan-tcheu to spend the second winter at the Humbum monastery, close by Si-nin. The third summer was spent for the return journey, which was made *viâ* Kuku-nor, across the mountains which separate the Tsaidam from the Mongolian plateau, and the cities of Han-tcheu and Su-tcheu. Then, taking a course due north, the expedition crossed the Gobi, as also several ridges continuing the Ek-tag Altai in the east, and the Hanghai ridge, and reached the Orkhon River, whence it proceeded to Kiakhta and across Siberia to Russia.

The Peking plain, covered with fertile loess, is separated by a series of three ridges built up of gneisses and limestones, from the plateau of the Ordos, watered by the middle Hoang-ho. Of Europeans, only M. Przewalski, the missionary Huc, and M. Potanin's expedition have visited the Ordos—a plateau about 3300 feet high, covered with shifting sands, the best part of which is on their eastern border. Owing to the moistness brought by the numerous streams which flow towards the Hoang-ho, the sands on the eastern border are not so bad as those described further west by M. Przewalski, and the *barkhans* are covered with bushes of *Shyavyk*, *Artemisiæ*, *Hedysarum lævi*, and thickets of the *Pugionium cornutum*—a new shrub discovered by Przewalski; sometimes dark growths of Thuja cover the *barkhans*. The hollows between the sandy hills are either covered with some bushes or occupied by the fields of the Mongols, who chiefly grow *setaria*, buckwheat, and hemp. The wet depressions, covered by meadow-grasses and partly with Halophytes, and called *tchaidams*, are enlivened by the herds and the mud huts of the half-nomadic Mongols. The sands are steadily moved by the winds from the south-west towards the north-east, and this constant motion explains why the Chinese gave to the sand-desert the name of Sha-he, or "River of Sand."

In the highlands which connect the Tibet mountains with those of Shan-si the expedition spent fifty days. Thick layers of loess cover there the horizontal layers of salt-bearing sandstones and conglomerates. The region is a bigh plateau deeply burrowed by the *cañons* of the rivers, which sometimes are 2000 feet deep, and are cut both through the loess and the sandstones. The narrow *cañons* are mostly waterless, while the broader ravines are watered by rivers and therefore are the seat of many villages. There is little wind or rain, and the atmosphere is charged with dust.

In Tibet the expedition crossed only the Amdo plateau, separated from the Mongolian plateau by the Nan-shan ridge. For 400 miles the expedition crossed there a region the lowest parts of which rise above 7000 and 8000 feet. Even the Hoang-ho at Gui-dui has an altitude of 7600 feet, and the valley of the E-tsin at the Pabor-ta-sy monastery is 8000 feet high; the valleys of the Urunvu and the Tumun-guan are at altitudes of from more than 9000 to 10,000 feet. The highest parts of the plateau rise, however, to 12,000 feet, and Lake Kuku-nor is spreading its waters at the height of Alpine peaks, *i.e.* 10,700 feet. Still higher grassy plateaus, where it never rains but often snows, and marshes spread over large areas, rise to the south of the lake. Only a few of the mountain-ridges which inclose this plateau are snow-clad. It has a quite original flora, discovered by General Przewalski. Forests are few; as to the high meadows, they are inhabited by nomad Tangutes, and, on lower levels, by a mixed population of Chinese and settled Mongols described under the name of Daldas.

The Alpine highlands watered by the northern tributaries of the Blue River, which separate the Amdo high plateau from the Chinese lowlands, are the most picturesque part of China. The routes which cannot follow the bottoms of the narrow and rocky valleys pass over the mountains, flights of steps being cut in the rocks, or wooden balconies being built along the steep slopes of the rocky hills. Suspended bridges, swinging under the weight of a mule, cross streams which flow in a succession of rapids and waterfalls. The Chinese monsoons deposit all their moistness on the south-eastern slopes of the mountains; thick forests, of Conifers on higher levels and of deciduous trees lower down, clothe the mountain slopes. Maples, lime-trees, oaks, *Helwingiæ*, and a number of shrubs and climbing plants are growing in impracticable thickets, while all crags are thickly covered with ferns, mosses, and orchids. Mollusks (*Bulymus* and *Helix*) cover the crags by thousands. And finally at the foot of the mountains the sub-tropical flora—palms, bamboos, banana-trees, and tea-trees—makes its appearance.

The villages and the towns—clean and well-watered—are strikingly picturesque, as the houses (with windows, like our European dwellings) are built in the shape of amphitheatres on the slopes of the steep forest-clothed hills. In some towns the roofs of the houses are the workshops and sitting-places of the inhabitants. The valley of the "Golden Lakes"—Kser-ntso—with its background of snowy peaks is especially picturesque.

As to the region crossed between the Amdo plateau and Kiakhta, it is sharply divided into two parts. The southern is a true desert, which stretches towards the north as far as the Khangai Mountains. The Nan-shan rises as an immense snow-clad wall on its southern border; then comes a narrow strip of inhabited and cultivated land, which is followed by a gravelly desert, where only a few trees of *Haloxylon Ammodendron*, and bushes of *Calligonum* and *Ephedra* grow here and there, while the course of the E-tsin is marked by narrow strips of meadows covered with *Elymus*. The depression of the E-tsin, which flows into the Gashiun-nor, has an altitude of only about 3000 feet, and it is bordered in the north by the Tostu ridge, and three other parallel ridges, of which the northern is snow-clad. The valleys which separate these four ridges are waterless; old river-beds, now dry, are seen on their bottoms, but even the *Haloxylon* forests which formerly grew in their valleys are now disappearing, only decayed trees having been seen by the expedition.

As to the plateau in the north of the Khangai Mountains, it is covered with rich meadows, while the slopes of the hills are clothed with forests of larch; the Siberian cedar-tree also makes its appearance. In the lower valleys the Mongols carry on some agriculture.

The above account is followed by an ethnographical sketch of the Ordos-Mongols and the Daldas.

The results obtained by the expedition are very important. A survey has been made of a stretch of no less than 4400 miles. Latitudes and longitudes have been determined at sixty-nine places. Two hundred photographs, 700 specimens of mammals and birds, a bulky herbarium, and rich collections of lizards, insects, mollusks, and rocks have been brought in. M. Berezovsky still remains in the region he has become so fond of, and he wrote last February, from Hoi-siang, that his journeys about Si-ning and Tai-tchan have enriched his collection with 500 more specimens of birds, some of which are very interesting.

P. A. K.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 17.—"Specific Inductive Capacity." By J. Hopkinson, M.A., D.Sc., F.R.S.

Colza Oil.—This oil has been found not to insulate sufficiently well for a test by the method of my former paper. Most samples, however, were sufficiently insulating for the present method. Seven samples were tested with the following mean results:—

No. 1. This oil was kindly procured direct from Italy for these experiments by Mr. J. C. Field, and was tested as supplied to me—

$$K = 3 \cdot 10.$$

No. 2 was purchased from Mr. Sugg, and tested as supplied—

$$K = 3 \cdot 14.$$

No. 3 was purchased from Messrs. Griffin, and was dried over anhydrous copper sulphate—

$$K = 3 \cdot 23.$$

No. 4 was refined rape oil purchased from Messrs. Pinchin and Johnson, and tested as supplied—

$$K = 3 \cdot 08.$$

No. 5 was the same oil as No. 4, but dried over anhydrous copper sulphate—

$$K = 3 \cdot 07.$$

No. 6 was unrefined rape purchased from Messrs. Pinchin and Johnson, and tested as supplied, the insulation being bad, but still not so bad as to prevent testing—

$$K = 3 \cdot 12.$$

No. 7. The same oil dried over sulphate of copper—

$$K = 3 \cdot 09.$$

Omitting No. 3, which I cannot indeed say of my own knowledge was pure colza oil at all, we may, I think, conclude that the specific inductive capacity of colza oil lies between 3·07 and 3·14.

Prof. Quincke gives 2·385 for the method of attraction between the plates of a condenser, 3·296 for the method of lateral compression of a bubble of gas. Palaz (*La Lumière Électrique*, vol. xxi. 1886, p. 97) gives 3·027.

Olive Oil.—The sample was supplied me by Mr. J. C. Field—

$$K = 3 \cdot 15.$$

The result I obtained by another method in 1880 was 3·16.

Two other oils were supplied to me by Mr. J. C. Field.

Arachide.—K = 3·17.

Sesame.—K = 3·17.

A commercial sample of *raw linseed oil* gave K = 3·37.

Two samples of *castor oil* were tried: one newly purchased gave K = 4·82; the other had been in the laboratory a long time, and was dried over copper sulphate—

$$K = 4 \cdot 84.$$

The result of my earlier experiments for castor oil was 4·78; the result obtained subsequently by Cohen and Arons (*Wiedemann's Annalen*, vol. xxviii. p. 474) is 4·43. Palaz gives 4·610.

Ether.—This substance as purchased, reputed chemically pure, does not insulate sufficiently well for experiment. I placed a sample, purchased from Hopkin and Williams as pure, over quicklime, and then tested it. At first it insulated fairly well, and gave K = 4·75. In the course of a very few minutes K = 4·93, the insulation having declined so that observation was doubtful. After the lapse of a few minutes more observations became impossible. Prof. Quincke in his first paper gives 4·623 and 4·660, and 4·394 in his second paper.

Bisulphide of Carbon.—The sample was purchased from Hopkin and Williams, and tested as it was received—

$$K = 2 \cdot 67.$$

Prof. Quincke finds 2·669 and 2·743 in his first paper, and 2·623 in his second. Palaz gives 2·609.

Amylene.—Purchased from Burgoyne and Company—

$$K = 2 \cdot 05.$$

The refractive (μ) index for line D is 1·3800,

$$\mu^2 = 1 \cdot 9044.$$

Of the benzol series four were tested: *benzol*, *toluol*, *xylol*, obtained from Hopkin and Williams, *cymol* from Burgoyne and Company.

In the following table the first column gives my own results, the second those of Palaz, the third my own determinations of the refractive index for line D at a temperature of 17°·5 C., and the fourth the square of the refractive index:—

			μ	μ^2
Benzol	2·38	2·338	1·5038	2·2614
Toluol	2·42	2·365	1·4990	2·2470
Xylol	2·39	—	1·4913	2·2238
Cymol	2·25	—	1·4918	2·2254

For benzol Silow found 2·25, and Quincke finds 2·374.

Linnean Society, November 17.—Prof. St. George Mivart, F.R.S., Vice-President, in the chair.—Mr. A. Bennett drew attention to new British plants, viz. (1) *Arabis alpina*, gathered on the Cuchillin Mountains, Isle of Skye; (2) *Juncus alpina*, obtained in Perthshire; and (3) *Juncus tenuis*, got near Galloway, Kirkcudbrightshire.—Mr. W. H. Beeby made remarks on *Carex cæspitosa* from Shetland.—Photographs of a branched palm (*Borassus flabelliformis*) was shown for Surgeon-General Bidie, of Madras, and a letter thereon read. The tree is growing near Tanjore, at a village named Paducottah, and is remarkable in being divided into eight branches.—Mr. W. Wilson sent for exhibition branches with ripe berries of *Taxus baccata*, and its variety *hybernica*, produced by natural cross-fertilization: these were grown in Central Aberdeenshire.—Mr. T. Christy showed a new species of *Strophanthus* from the Niger; it is distinguished by its brown velvety seed and intensely bitter taste.—Mr. D. Morris exhibited the following specimens: (1) a fibre from Vera Cruz, named Broom Root, which examination showed to be the root fibres of *Epicampus macroura*, known as "Raviz de Zacaton" by the Mexicans, its yearly value in export is £60,000; (2) another Mexican fibre, "Ixtli," much used for nail-brushes, &c., in Britain, by reason of its short tough fibre, is found by the Kew authorities to be derived from *Agave heteracantha.*—Mr. J. G. Baker showed *Lycopodium albidum*, a new species from the Andes of Ecuador; it is allied to *L. clavatum*, but without chlorophyll except at the base. He also showed *Neobaronia xiphoclades*, a new Papilionaceous plant from Madagascar, obtained by the Rev. R. Baron.—A paper was read by Mr. P. Geddes, on certain factors of variation in plants and animals.—Then followed a paper on the Copepoda of Madeira and the Canary Islands, by Mr. I. C. Thompson. In all, sixty-five species were obtained. Of these, six are new to science, and three probably of generic significance. Twenty-three are known in British waters, and of these fourteen belong to the family Harpacticidæ. There is a similarity in species in the different islands, but the numbers of each vary greatly.

Geological Society, November 9.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—Note on the so-called "Soapstone" of Fiji, by Henry B. Brady, F.R.S. The Suva deposit, which has a composition very similar to that of the volcanic muds at present forming around oceanic islands in the Pacific, is friable and easily disintegrated. The colour ranges from nearly white to dark gray, the mass being usually speckled with minerals of a darker hue. Under the microscope the rock presents the character of a fine siliceous mud with crystals of augite, &c.,

together with the sparsely scattered tests of Foraminifera. The approximate chemical composition of typical specimens is:—Silica, 50 per cent.; alumina, 18 per cent.; lime and magnesia, from 5 to 6 per cent.; ferric oxide, from 3 to 8 per cent.; water, 16 per cent., with a small proportion of alkalies, chiefly potash, and but small trace of carbonates. The author's attention was chiefly directed to the common gray friable rocks which may be softened in water and washed on a sieve, the residue consisting mainly of Foraminifera with a few Ostracoda. Of three specimens examined, (1) is a light-gray rock from close to the sea-level; (2) of a lighter colour, from about 100 feet elevation; (3) is nearly white and somewhat harder, and was derived from an intermediate point. So far as the Microzoa are concerned, the first two present no differences which might not be observed in dredgings from the recent sea-bottom, taken at similar depths a little distance apart. The third appears to have been deposited in somewhat deeper water. There is a marked scarcity of arenaceous Foraminifera. Then followed notes on the rarer and more interesting species, together with a list of the ninety-two species of Foraminifera found. Of these, eighty-seven are forms still living in the neighbourhood of the Pacific islands. Two of the remaining five are new to science, and the rest extremely rare. The author concluded that these deposits are of Post-Tertiary age, formed at depths of from 150 to 200 fathoms in the neighbourhood of a volcanic region. The following new or little-known species were selected for illustration:—*Ellipsoidina ellipsoides*, var. *oblonga*, Seguenza; *Haplophragmium rugosum*, D'Orb.; *Ehrenbergina bicornis*, nov.; *Sphæroidina ornata*, nov. The President hoped that this paper might be regarded as one of the first-fruits of travels undertaken by the author for the purpose of investigating the interesting deposits of this nature. Prof. Rupert Jones agreed that this was a valuable instalment of work to be expected. The peculiar Foraminifer specially mentioned by Mr. Brady (*Ellipsoidina ellipsoides*, var. *oblonga*, Seguenza) must have connections, so that, as the author has intimated, the interest attached to it was not yet wholly worked out.—On some results of pressure and of intrusive granite in stratified Palæozoic rocks near Morlaix, in Brittany, by Prof. T. G. Bonney, F.R.S.—On the position of the Obermittweida conglomerate, by Prof. T. McK. Hughes.—On the Obermittweida conglomerate: its composition and alteration, by Prof. T. G. Bonney, F.R.S.—Notes on a part of the Huronian series in the neighbourhood of Sudbury (Canada), by Prof. T. G. Bonney, F.R.S. The specimens noticed by the author were in part collected by him in the summer of 1884, when the Canada Pacific Railway was in process of construction, and in part subsequently supplied to him by the kindness of Dr. Selwyn, Director-General of the Geological Survey of Canada. The eastern edge of the district assigned to the Huronian consists of rocks, which may possibly be part of the Laurentian series modified by pressure. But after crossing a belt of these, barely a mile wide, there is no further room for doubt. All the rocks for many miles are distinctly fragmental, except certain intrusive diabases or diorites. These fragmental rocks are grits, conglomerates, and breccias, which are described as far as about two miles west of Sudbury. The included fragments in these rocks appear to have undergone some alterations subsequent to consolidation: these are described. In some cases the changes appear to be anterior to the formation of the fragments. The matrix also has undergone some change, chiefly the enlargement of quartz grains, and the development or completion of mica-flakes, as in the Obermittweida rock. The author gave some notes on other specimens collected by him along the railway, further west, and on those supplied to him from near Lake Huron by Dr. Selwyn. As a rule these are but little altered. Some contain fragments of igneous rocks, apparently lavas. The author discusses the significance of the changes in these rocks, as bearing on general questions of metamorphism, and states that, in his opinion, the name Huronian, at present, includes either a series of such great thickness that the lower beds are more highly altered than the higher, or else two distinct series; and he inclines to the latter view. Both, however, must be separated from the Laurentian by a great interval of time, and neither exhibits metamorphism comparable with that of a series of schists and gneisses, like the so-called Montalban. The newer reminds him often of the English Pebidians. After the reading of this paper there was a discussion, in which the President, Dr. Geikie, Mr. Rutley, and others took part.

Royal Meteorological Society, November 16.—Mr. W. Ellis, President, in the chair.—The following papers were read:—The use of the spectroscope as a hygrometer simplified and explained, by Mr. F. W. Cory. The object of this paper is to suggest as simple a way as possible of using the spectroscope as a hygrometer in order to facilitate its introduction amongst observers as a standard meteorological instrument. The best form of hygro-spectroscope as a recognized standard for the purpose of investigating and scrutinizing the changes of the three parts of the spectrum mentioned is that originally termed by Mr. Rand Capron "The Rainband Spectroscope." It ought to have a fixed slit, and in addition a milled wheel at the side for the easier adjustment of the focus. The author concludes by giving a set of hints to observers for taking weather observations with a pocket spectroscope.—Rainfall on and around Table Mountain, Cape Town, Cape Colony, by Mr. J. G. Gamble. The author calls attention to the great and in some respects peculiar differences that exist between the quantity of rain that is registered on and around Table Mountain. The most striking feature is the small fall on the signal hill. The signal hill, otherwise called "the Lion's Rump," lies to the west of Cape Town, between it and the Atlantic. The average annual fall there is only 15 inches, while the fall at the western foot is 21 inches, and in Cape Town 27 inches. The signal hill is 1143 feet above the sea. The fall at Platteklip, on the northern slope of Table Mountain, overlooking Cape Town and 550 feet above the sea, is considerable, namely 45 inches. The greatest fall is at Waai Kopje, about half a mile to the southward of the highest point of the mountain, at an elevation of 3100 feet, or 450 feet below the top. Another station on Table Mountain further south—that is, to the leeward in the rainy season—and 2500 feet above sea-level, has only 39 inches. The eastern suburbs, Rondebosch, Newlands, and Wynberg, all have a comparatively abundant rainfall, 40 to 50 inches and upwards, the greater part of which falls in winter time.—On the cause of the diurnal oscillation of the barometer, by Dr. R. Lawson. The object of this paper is to show that the durnal oscillation of the barometer is mainly due to the combination of the earth's rotation with its orbital motion.

PARIS.

Academy of Sciences, November 28.—M. Janssen in the chair.—On the most general equations of double refraction compatible with Fresnel's wave surface, by M. Maurice Lévy. Whatever view be taken of polarized light in a plane, whether it be regarded as the effect of an elastic or electro-magnetic disturbance, whether it result from rectilinear vibrations or from mean rotations (vortices), or from any other cause, it is certain, as remarked by Maxwell, that this cause is measurable by a quantity which is in the nature of a vector. This vector, whether it be a vibration or a force, the axis of a vortex or of a magnetic momentum, or aught else, is here called a luminous vector, and an attempt is made to determine its most general expression compatible with Fresnel's wave surface.—On the movement of cirri and their relations to cyclones, by M. H. Faye. These phenomena are compared to the action of a river on which floating ice is borne along. Whenever an eddy is formed, the nearest fragments of ice are seen to be drawn within its influence, following its spiral movements and disappearing with it on reaching the centre, while the masses lying beyond its influence continue to drift with the stream. Precisely analogous phenomena are presented by the cirri carried along by atmospheric currents in the higher regions. They are in the same way sucked down by the gyratory action of the whirlwind, giving rise in the lower regions to heavy rains, hail, and thunderstorms, while the more distant clouds continue to follow the general course of the wind.—Researches on the importance of consumptive patients breathing a pure air uncontaminated by pulmonary exhalations, by MM. Brown-Séquard and d'Arsonval. These remarks are made in connection with an apparatus submitted to the Academy, which has been constructed for the purpose of removing from bedrooms all the air exhaled by one or more persons. The importance is shown of thus purifying sick-rooms, hospital wards, &c., especially when occupied by patients suffering from affections of the lungs.—On a class of differential equations, by M. R. Liouville. Here are studied more especially the differential equations, amongst which are comprised all those of the geodetic lines.—Action of vanadic acid on the fluoride of potassium, by M. A. Ditte. It is shown that vanadic acid in combination with the fluoride of potassium yields compound substances more or less rich in fluoride. But in the presence of oxygen a certain quantity of potassa is de-

veloped, which forms vanadates with a part of the vanadic acid employed in the process.—Ammonical cyanides of zinc, by M. Raoul Varet. The chloride, bromide, and iodide of zinc combined with ammonia yield a relatively large number of compound substances. But with the cyanide of zinc, whatever be the conditions, the only substances obtained are $ZnCy,NH_3HO$ when the reaction takes place in the presence of water, and $ZnCy, NH_2$ in all other cases.—Application of a method of de Senarmont to the reproduction of celestine and anglesite by the wet process, by M. L. Bourgeois. The process by means of which de Senarmont obtained artificial crystals of barytine is here applied to the production of the allied minerals, celestine and anglesite.—On the importance of the nutritive function in determining the distinction between plants and animals amongst the lower organisms, by M. P. A. Dangeard. The Chytridineæ and the Chlamidomonadineæ, the two primary groups of the vegetable kingdom, are both connected below with the Flagellæ, branching off upwards one to the Algæ the other to the Fungus group. It is here shown that by the process of nutrition alone is it possible to determine the point where plant and animal become differentiated.—On the suckers of the Rhinantheæ and Santalaceæ, by M. Leclerc du Sablon. These hold an intermediate position between non-parasitic and true parasitic plants, drawing their nutriment both through their roots and through suckers from other plants. The present observations deal exclusively with the suckers and their various functions.—On the discovery of carboniferous formations with marine and vegetable fossils in the neighbourhood of Raon-sur-Plaine, by M. Bleicher. The recent discovery of coal in this district supplies the connecting link between the carboniferous measures of the Bruche and Rabodeau valleys (Alsace and Lorraine).

BERLIN.

Physiological Society, November 4.—Prof. du Bois Reymond, President, in the chair.—Dr. Goldschneider spoke on the fact, which has been known for a long time, that when carbonic acid gas is allowed to come in contact with the skin it produces a greater sensation of warmth than air of the same temperature. He has carried out a prolonged series of experiments to determine the cause of this increased sensation of heat. He examined first the purely physical factors which might have some influence on the observed facts—namely, the moistness, specific heat, and heat-absorption by the gases. When he compared the sensation of heat produced by moist air with that produced by dry air, he found that the former always seemed the greater; the difference between the two might be as much as 5° C. to 6° C. when the air was at a higher temperature than that of the skin. Thus, air at 35° C. whose saturation with moisture was 80 produced the same sensation of heat as air at 41° C. whose saturation was only 30. When experimenting with carbonic acid gas he found that a difference of 40 in the saturation produced a difference in the resulting sensation of heat corresponding to 2° to 3° of temperature. But even when equally moist or dry air and carbonic acid gas were allowed to act on the skin the sensation of heat produced by the latter was always the greater. It does not seem possible to explain the greater sensation of heat with carbonic acid gas by reference to the extremely small differences of specific heat of air and this gas, still less by reference to their somewhat greater coefficients of heat absorption. He also investigated the effect of the more ready absorption of carbonic acid gas by fluids, by removing the epidermis with a blister on a circumscribed portion of the skin and allowing the gas to act upon this place. The carbonic acid gas was speedily absorbed by the lymph, but it still produced a sensation of greater heat even when all moisture was removed from the surface exposed by the blister. He hence considers that the purely physical properties of the gas will not suffice to explain its remarkable influence on the sensory nerves for heat. Dr. Goldschneider next investigated the physiological factors which might suffice to explain the observed phenomenon. He proved that there is no recognizable objective rise of temperature under the influence of the carbonic acid gas. It is true that he observed now and again a distinct dilatation of the blood-vessels, but this was by no means constant, and not sufficient to account for the increased sensation of heat. He proved however as has been observed by many physiologists, that the carbonic acid gas has a direct effect upon the sensory nerves; but in contrast to the results of others, who attribute an anæsthetic action to this gas, he observed that at first it produces a hyperæsthesia of those nerves specially connected with the production of heat sensations, and then this makes way for an anæsthesia. The nerves connected with heat sensations were more strongly stimulated than those connected with sensations of cold. The speaker summed up the results of his extremely numerous experiments by urging that in addition to the greater absorption of heat by the carbonic acid gas and its power of producing hyperæmia of the skin, its action is to be explained chiefly by its direct chemical action on the endings of the nerves concerned in the production of sensations of heat. This therefore is to be regarded as the cause of the observed phenomenon that when carbonic acid gas is brought into contact with the skin it produces a greater sensation of heat than does the contact of equally warm and equally dry air.

CONTENTS.

THURSDAY, DECEMBER 15, 1887.

THE HORTICULTURAL SOCIETY.

THE Horticultural Society of London was founded in 1804, among the first members being Sir Joseph Banks. Its objects were "to collect every information respecting the culture and treatment of all plants and trees, as well culinary as ornamental," and "to foster and encourage every branch of horticulture, and all the arts connected with it." The Earl of Dartmouth was the first President. The Society was incorporated by Royal Charter in 1809. In 1820 the Society purchased 21 Regent Street, which was its London home for forty years. In 1822 it obtained a lease of the present Gardens at Chiswick, which have been cultivated and embellished under the Society's auspices for upwards of sixty-five years.

At the conclusion of the war in 1815 the Society began to import plants from abroad, and this country owes to its early exertions many of the beautiful camellias, azaleas, peonies, roses, and chrysanthemums which are natives of the East, and among other plants the *Wistaria* (*Glycine*) *sinensis*, a lovely creeper now quite at home in England. Indeed, one cannot take a day's ride anywhere through the country without meeting some of the beautiful introductions of the Society. Among the collectors sent out by the Society was Douglas, to whose energy the country owes *Pinus Lambertiana*, *P. insignis*, *P. ponderosa*, *P. nobilis*, *P. Douglasii*, &c.

Dr. Lindley, one of the most eminent botanists this country has ever produced, was appointed Assistant Secretary in 1822, and continued connected with the Society until his death in 1865. No account of the early days of the Society would be complete without a record of the fruits of Fortune's journeys, under its auspices, in China. Not only did he send innumerable valuable plants home, but his travels in the Chinese tea-country were the direct cause of the introduction of tea-cultivation into India.

In 1839 the Duke of Devonshire was elected President, on the death of Mr. Andrew Knight, who had been President for twenty-seven years, and to whom the Society owed much. In January 1858 the Duke of Devonshire died, and H.R.H. the Prince Consort graciously consented to succeed him. The establishment of the Society at South Kensington, under H.R.H.'s guidance and direction, is so comparatively recent an event that it is not necessary to refer to it at length. At first the prospect was promising, and had not the Prince Consort's life been cut short, the result might have been very different from what it has proved. But the money expended on the buildings and the gardens at South Kensington, from the funds of the Society, was little short of £100,000—a sum which, with the experience we now have, no one would dream of devoting to such purposes. This enormous expenditure hung like a millstone round the neck of the Society, which soon found itself unable to pay the interest on the money borrowed to meet it. The result was that, under a clause of the Society's agreement with the Commissioners of the 1851 Exhibition, the latter body resumed possession of the Gardens six years ago, and the money spent upon them by the Society was swept away at a blow.

Nevertheless the horticultural work of the Society has been carried on with undiminished energy. This surely is the proper and legitimate work of such a Society. Every departure it takes from its true functions alienates the sympathy and support of those to whom it properly looks, and to promote whose objects it exists. Since the Society has been established at South Kensington, its activity in horticultural work has been as marked as even in its most prosperous times. Many thousands of new plants, fruits, and vegetables have been submitted to the examination and the verdict of the Society's Fruit and Floral Committees, which consist of practical men, of the greatest knowledge and experience in their several departments. The value attaching to "First-Class Certificates" is shown by the care nurserymen take to record them in their catalogues. At Chiswick a long series of elaborate trials and experiments have been carried on with fruit, vegetables, and plants, whereby useful and profitable varieties have been selected and their qualities established, and inferior varieties ear-marked.

Although the Society has been unable to hold great shows owing to the loss entailed by them, it has held fortnightly shows in summer and monthly shows in winter, at which a vast number of new plants and new introductions have been seen for the first time. Such shows, though small, are often far more interesting to horticulturists than the big shows which were the fashion formerly.

It may well be asked why, if the Society can give so good an account of itself, it should be in any difficulty? The answer is that its troubles are due to its connection with South Kensington. It cannot be said that the Commissioners of the 1851 Exhibition have behaved with any conspicuous liberality to the Society. Perhaps they could not do so, as they have said that it was necessary for them to make an income out of the Royal Horticultural Gardens. But the connection with South Kensington has made it necessary for the Society to meet the views of local subscribers, who were not horticulturists; and, moreover, it has led to the Society being saddled with a charter, which prevents its expansion and adaptation to altered times and circumstances.

The views of the Council are set forth in general terms in the statement and appeal which we print elsewhere The interest in horticulture in the United Kingdom grows and spreads without check. Surely the horticulturists of the wealthiest country in the world will gladly provide the very moderate sum required for the maintenance of a Society which has done much for them, is still doing much, and has before it untold possibilities of usefulness.

BALBIN'S QUATERNIONS.

Elementos de Calculo de los Cuaterniones, &c. Por Valentin Balbin, Doctor en Ciencias, &c. (Buenos Ayres: imprenta de M. Biedma, 1887.)

ALL praise is due to the Argentine Republic for its institution of a University in which the Faculty of Sciences is endowed with a chair of the higher mathematics.

The book before us is the outcome of one of the courses of lectures which the holder of that chair, Dr.

Valentin Balbin, delivered to an audience comprising several of his colleagues. The volume, written in Spanish, has been printed at Buenos Ayres, and in size (xix. and 359 pages), and in quality of paper and print, presents a very handsome appearance.

In his preface the author informs us that in his opinion the calculus of quaternions is the best vehicle for the teaching of applied mathematics, and that therefore he has had recourse to Sir William Rowan Hamilton's beautiful invention. The author is aware of the fact that he is the first to introduce quaternions into the Spanish scientific literature, and for this reason he aims at presenting the theory from its very elements up to its higher branches of application.

In the matter of notations we are also informed that those of Hamilton and of Prof. P. G. Tait have been scrupulously adhered to, and that, in one word, the author has not found it advisable to follow those of M. Hoüel and of M. Laisant. It may not be known to everybody that these two French mathematicians have in their publications (1874, 1877, 1881) adopted a thorough reversal of Hamilton's lettering. In the place of the inventor's Greek letters, they use Roman characters (X for ρ, Y for σ, A for α, &c.); and in the place of the handy S, V, T, U, they put black-letter symbols, which are at once difficult to write, and tiring to the eyesight. These are what they call "slight alterations" or "improvements."

Again, they upset the rule about the relative appellation of the factors of a product. Our author (p. 40) states the Hamiltonian rule, and justifies it by the simple example drawn from $a + a = 2a$, where (according to everybody's ideas) the coefficient 2 is the multiplier, and a the multiplicand. According to the "innovated" rule one ought to write $a + a = a \times 2$.

The rule just named makes its influence felt more particularly in the establishment of the operator of conical rotation, and here we are sorry to find that our author falls a victim to a delusion. Instead of Hamilton's well-established $q(\ \ )q^{-1}$, he arrives at the inverse $q^{-1}(\ \ )q$ (at p. 296), and uses it under this form through several pages (up to p. 303). This comes from following M. Laisant's text, and forgetting his own rule. In M. Hoüel's opinion, "nothing is easier than to pass from one system (his own system) to the other"; nevertheless, such passage requires to be nicely managed, because by it the expression for the instantaneous axis is affected, and we might ask whether it be fair to introduce a source of confusion into a theory which in itself is difficult enough. Our author does not introduce us to the searching treatment which Prof. Tait has devoted to the question of the movement of a solid about its centre of mass ("Elementary Treatise," &c., second edition, §§ 383-400). M. Balbin's treatment of that question is very curtailed, and we might be inclined to attribute this shortness to a feeling of distrust, otherwise how could we understand his utterance, at p. 87, where he says forcibly, "Some simplifications, particularly in the physico-mathematical applications, must be made in the future as to the matter of symbols" (*se hagan*, imperative of *hacer*).

The more we consider the innovations, the more are we convinced that their proposer and his follower, publishing in 1874 and 1881, had not fully realized the extent and importance of the researches which, during many years, had been expressed in what we may term the Hamiltonian notations. In 1862 no less a Frenchman than M. Allégret set the example of following these last-named, and that precedent ought to have been adhered to. As it is, students of MM. Hoüel and Laisant will be hampered by the French notations when they approach those rich mines of information contained in such unique classics of the quaternion method as Hamilton's "Lectures" and "Elements," and the "Elementary Treatise on Quaternions," by Prof. Tait.

Let us now try to give some idea of the contents of the volume. For the English student these are all contained in the sources known to him. First "The Introduction to Quaternions," by Kelland and Tait. This work has been reproduced in its whole extent, with the exception of Chapter X., due to Prof. Tait alone. The author acknowledges in several instances (pp. 114, 120, 252) his special indebtedness to the English authors; and his translations are adequate. Perhaps, however, he knows them best through the medium of M. Laisant's reproduction of a great part of Kelland's work (with acknowledgments in the preface, tempered by the praise of the new notations).

In the second place, in the treatment of linear vector-functions and the resolution of equations involving them, which were originally given by Hamilton, there are clear indications that our author has taken his text from works where the innovated notations reign supreme; some traces of x (at pp. 183, 184, 193), for instance, are left standing in the place of ρ, and are contained concurrently with ρ in one and the same equation, in several cases; no explanation about the signification of x being given. A similar fate befell the vector ρ, at p. 138, where x is put into its place by being defined: $x = ix_1 + jx_2 + kx_3$. Under this form x is introduced into the operator ∇, which in its turn undergoes a little adaptation. But all this is not the promised adhering to Hamiltonian notations.

The solution of the vector-equation $\Sigma\alpha S\beta\rho = \gamma$ is gone partially into; but the calculation of the coefficient m of the cubic (at p. 192) contains an inexact intermediate step, and the coefficient m_1 is given with the wrong sign. Finally the solution of the proposed equation (p. 193) is incorrect, owing to the absence of the factor γ in the first term of the second member. These three inaccuracies can be traced to one of the French texts.

In the third place, curves in space, and centres of curvature of those curves, and of plane sections of surfaces, subjects exhausted by Hamilton and by Prof. Tait, have been treated by our author with the help of Dr. Graefe's little volume on Quaternions (Leipzig, 1883). We might take exception to Dr. Graefe's deduction (p. 236 of Balbin's) of Meusnier's theorem, as well as of that of the curvature of a normal section of a surface. To replace a scalar, say $S\alpha\beta$, by $\frac{1}{2}(\alpha\beta + \beta\alpha)$, in order to procure an expression of the product $\alpha\beta$ separately, seems to us to be forsaking the spirit of the method of quaternions; the expression for $S\alpha\beta$ being given, and that of $V\alpha\beta$ being deducible from other considerations, it would have been far simpler to deduce $\alpha\beta$ by forming the sum $S\alpha\beta + V\alpha\beta$ straight forward. Some reticences (p. 236), and even some inaccuracies, in the text of Dr. Graefe, have been

reproduced also by M. Balbin at pp. 136, 138, 247. Dr. Graefe, like other German authors on quaternions, reproduces a great part of the "Introduction to Quaternions" by Kelland and Tait, and also some parts of the "Elementary Treatise" by Prof. Tait; but after having once pronounced the name of Hamilton, he has done all in the matter of acknowledgment, and the name of Tait is not to be found in the little volume.

We now come to the fourth class of subjects treated by our Argentine author. This comprises kinematical, statical, and dynamical questions. Here we meet with the treatment, in good form, of questions included in Hamilton's "Elements," and in the second edition (1873) of Prof. Tait's "Elementary Treatise." Of this last source of information our author seems to have only a second-hand knowledge: he reproduces verbatim the contents of § 405 of the "Elementary Treatise" (second edition), but he attributes the authorship of it to M. Laisant. Evidently, M. Laisant reproduced this § 405, which treats of Foucault's pendulum, but the origin of the treatment is to be found in the Proceedings of the Royal Society of Edinburgh of 1869, *auctore* P. G. Tait. Again, by the small-print note at p. 303 we have another indication that our author was unacquainted with the contents of the two or three last chapters in the second edition of the "Treatise." Had he known them, he could not have withheld a more special acknowledgment of results worked out by the immediate follower of Hamilton.

Prof. Tait certainly can claim to have been the first to make quaternions intelligible, not alone to ordinary students, but to advanced mathematicians—"such as have the [rare] gift of putting an entirely new physical question into symbols." But the Edinburgh Professor has particular claims to the thankfulness of students of the first-named category (the writer amongst them), for, under the plea of teaching the quaternion method, he has given them an insight into those physico-mathematical questions which are so unapproachable when obscured by the apparatus of Cartesian co-ordinates. When these questions are expressed and solved in quaternion language, they acquire a clearness and a conciseness which might well astonish their original proposers—Green, let us say, Ampère, Poinsot, even Newton, not to name living workers. We cannot be expected to enumerate the list of the questions treated; we will allude only to those in which the operator ∇ is pressed into services of such marvellous fecundity, to those in which the linear vector-functions play an eminent *rôle*, and to those in which the operator of conical rotation is such a powerful auxiliary.

The last chapter of the volume contains a painstaking record of the history of quaternions. The English reader will find much of this, and even more, in the article on "quaternions" in the "Encyclopædia Britannica." We may say that the imaginaries of algebra having done good service during the process of discovery, can be safely now banished from the principles and practice of the quaternion method—unless bi-quaternions are under treatment. In the ordinary applications of the method the extraction of the square root of the members of an equation such as $\epsilon^2 = -1$ (ϵ being a unit-vector) is looked upon as impracticable, and the reason is clearly this: the combination $\epsilon\epsilon$, represented by ϵ^2, is a symbol *sui generis* just as much as ϵ itself, and cannot be decomposed or attacked—to speak the language of chemistry—by the algebraical operation of extracting the square root of it. To assimilate a unit-vector with $\sqrt{-1}$, the square root of negative unity, is as if, in the differential calculus, one were to assimilate a derivate, $\frac{dy}{dx}$, with the symbol $\frac{0}{0}$ of indetermination. We cannot resist the temptation of helping our author to preserve a little curiosity in the history of the subject. The author records the verdict of an unnamed French mathematician, who says: "Quaternions have no sense in them, and to try to find for them a geometrical interpretation is as if one were to turn out a well-rounded phrase, and were afterwards to bethink oneself about the meaning to be put into the words. . . ." This, after all, is rivalled by the verdict of a German mathematician, who simply declared the quaternion method to be "eine Verirrung des menschlichen Geistes" (an aberration of the human intellect).

GUSTAVE PLARR.

CABLE-LAYING.

On a Surf-bound Coast; or, Cable-laying in the African Tropics. By Archer P. Crouch, B.A. Oxon. (London: Sampson Low, 1887.)

IT is somewhat remarkable that the business of making and laying submarine telegraph cables—which hitherto has been a monopoly of Great Britain, and employs large numbers of skilled workmen of all kinds, of scientific men, and of sailors—should be so little understood by people not directly connected with it. Yet the daily history of any cable-laying expedition, if faithfully written, would contain matter of engrossing interest for all readers. To secure a contract on advantageous terms requires diplomatic talent of a high order. For, although the business is a British monopoly and there is no competition with the foreigner, there is all the keener competition between the rival British companies. Further, the negotiations are almost always with Government departments, either home, colonial, or foreign, and are necessarily of a delicate character. In the history of any particular cable the preliminary diplomatic details would no doubt have by far the greatest interest for most readers, but it would be obviously indiscreet and unadvisable to publish them. In tendering for a cable against powerful competitors it is important to have as accurate a knowledge as possible of the depth of water and the nature of the bottom where the cable is to lie, in order to know exactly the lengths of the different types of cable which will have to be employed, and so to estimate the cost. In obtaining this knowledge the cable-laying companies have been the chief contributors to the science of deep-sea research, or oceanography. The contract obtained, the cable made, and the route determined on, the operation of laying has to be undertaken. When it is merely a question of laying a length of cable between two points over smooth ground, this is in most cases a very simple affair; although if the shore-ends of the cable have to be landed on exposed beaches, as is only too often the case, there is plenty of opportunity for thrilling incident and hair-breadth escape. The expedition in which Mr.

Crouch was engaged had for its object to connect a number of settlements on the West Coast of Africa from Bathurst to St. Paul de Loanda, and belonging to the British, French, Spanish, and Portuguese. Although it is fixed beforehand what places are to be connected, it is only when the ship arrives on the ground that the exact place of landing, the amount of assistance to be got from the shore, and a host of matters of minute local detail, but of great importance, can be settled, and to do so satisfactorily, expeditiously, and without friction, requires qualities of a very high order in the chief of the expedition. How difficulties were overcome, dangers met, and accidents repaired, in the course of the laying of one portion of the West African Company's cables is told in a pleasant and readable way in "On a Surf-bound Coast." Mr. Crouch carries his descriptions only as far as Cutanu, a French settlement lying between Accra and Lagos. From this place the cable was taken to the Portuguese islands St. Thomê and Principe, the French settlement on the Gaboon, and the Portuguese town St. Paul de Loanda; but this part of the expedition is reserved for description in a possible future volume.

The narrative begins with the start of the s.s. *Thracia* and her consort the *Pioneer* from the Thames, under the chief command of Mr. White. The names of persons and ships are purposely altered. The work really begins with their arrival at Bathurst, the chief British settlement in the Gambia district. In the previous year the cable had been laid as far south as the French settlement Conakry, about 70 miles north of Sierra Leone; and outside of Bathurst the cable, coming from the Cape Verde Island of St. Jago, had been joined to it, forming a T piece. Their first job was to cut out this piece, and run the three ends, leading respectively northwards to Dakar, westwards to St. Jago, and southwards to Conakry, into Bathurst. This affords the author an opportunity of describing the operations of "picking up" in shallow water, also of laying shore ends in protected water, and of splicing cables. In this Mr. Crouch acquits himself fairly well; indeed, it is very difficult to make intricate mechanical operations of the kind quite intelligible to the uninformed without the use of drawings. In the course of these operations the two ships each passed a portion of their time on the sand-banks, which are here plentiful and almost completely unsurveyed.

The next piece of work was connecting the French settlement Conakry with Sierra Leone. Here, again, there was no dearth of incident, as the *Pioneer*, in landing the shore end, went on a rocky patch, and was with difficulty got off. During the laying the cable got round the propeller, and might have caused great delay but for the promptitude and courage of Mr. White, who, without hesitation, went overboard and dived straight down to the propeller, and on coming up ordered "three half turns more in the same direction," when the cable came free. There are many other instances scattered through the book of the resource, energy, and perseverance required for success in this kind of work.

The *Pioneer* was obliged to return home, and the *Thracia* left Sierra Leone alone and proceeded round the coast, landing shore ends at Grand Bassam, Accra, and Cutanu or Appi. The company's larger steamer, the *Copperfield*, meanwhile came out with the bulk of the cable, and connected these shore ends. Mr. Crouch was transferred to the *Copperfield*, and assisted at the laying of a portion of these cables, and he was landed at Accra, along with two other members of the staff, to attend that end of the cable, which, for the time being, had a blind end buoyed out at sea. It was the duty of these gentlemen to watch night and day the spot of light on the scale of the galvanometer, so as to be ready to answer whenever the ship picked up the end and "called" them. The fatigue and monotony of this weary work of waiting and watching is well described. There are also interesting descriptions of Accra and its inhabitants. Indeed, the latter half of the book is by far the more interesting; there is more business in it and less of the jokes and chaff of the quarter-deck, which, though useful and even amnsing at the time, seldom possess sufficient permanent value to justify their being printed at any length.

The book, taking it all round, is a useful and entertaining one, and as a first attempt is altogether creditable and full of promise. In any future work the author should not be afraid of tiring the reader by careful and detailed description of any operation of interest on which he may be engaged. Outside of those directly connected with the business or the profession, the general reader knows nothing of the methods of laying and working submarine cables. J. Y. B.

TEXT-BOOK OF GUNNERY.

Text-book of Gunnery, 1887. By Major G. Mackinlay, R.A. (London: Printed for Her Majesty's Stationery Office by Harrison and Sons, 1887.)

TO realize the great alterations which have taken place in artillery in the last twenty years it will be necessary to compare the present work with the corresponding "Treatise on Artillery" of 1866, prepared for the use of the Practical Class, Royal Military Academy, in which there is no mention of rifled artillery, iron armour, or electro-ballistic apparatus, and the Practical Class were expected to go forth fully equipped to compete with any foreign enemy with the smooth-bore gun, the spherical projectile, the formulæ for penetration into earth, and such information on velocity and resistance as the ballistic pendulum could afford. If twenty years can make such alterations in the science of artillery, imagination attempts to penetrate the future and to gather some information as to the view in which the present treatise of 1887 will then be held.

Official treatises, however, must not be criticized according to the irreverent sceptical rules of modern scientific inquiry. The authors are prevented by military discipline from expressing any opinion on the merits of the weapons they describe, even when of an experimental nature. Thus the Armstrong rifled gun had been in serviceable use for seven or eight years, and Mr. Bashforth had been experimenting with his chronograph on elongated projectiles and the resistance of the air to their flight for nearly two years, before the appearance of the 1866 edition of the "Treatise on Artillery"; and, coming to the present edition, we find little or no mention of such important matters as steel shields for the protection of the gunners in the field against bullets (*vide* reports on the Boer War),

the importance of range-finders in lessening the amount of ammunition to be carried in the limbers, the dynamite gun for use in sieges, and other modern developments.

After the Battle of Waterloo we went comfortably to sleep on our laurels, and awoke to find ourselves engaged in the siege of Sebastopol with exactly the same weapons we had employed in the Peninsular War. Sebastopol with modern weapons could have been taken with one-tenth of the hundreds of millions that were lavished; so it is important for the future that the taxpayer should take an intelligent interest in military preparations and see that we are provided with the very best weapons that money can procure. Such an intelligent public has been educated in the Volunteer force, and these "men with muskets" are not prevented by military discipline from criticizing their muskets, or equipment in general; and it is to them that we owe the healthy criticism that has lately been exercised on our armaments and state of military preparation.

Hotspur's description of the regular military officer saying: "It was great pity, so it was, that villainous saltpetre should be digged out of the bowels of the harmless earth, which many a tall fellow had destroyed so cowardly; but for these vile guns," &c., is true to this day; for the modern artillery officer's pride in his gun varies inversely as the weight, for certain tangible reasons; and generally a soldier looked upon his weapons as something to keep clean and to drill with until some recent warfare taught him the importance of the despised musketry instruction. The officer's attention is fully occupied in attending to the drill and discipline of his men according to the regulations; and we find that the scientific development of methods of destruction is generally due to amateur civilians like Benjamin Robins, of Quaker extraction, the father of modern gunnery, and the Rev. Mr. Bashforth; while the Gatling gun is a product of Philadelphia, the City of Brotherly Love. Clerk's "Naval Tactics," written by John Clerk of Eldin, a relative of Prof. Clerk Maxwell, and an Edinburgh barrister, was the treatise which put a stop to the ineffective naval engagements of the last century—ineffective because culminating in the failure of the fleet to relieve, and the consequent surrender of, Yorktown.

Major Mackinlay's treatise appears to be very carefully compiled, and taking into account the restrictions under which the author works, it is fully up to date with the development of our own artillery; whether with the artillery of foreign countries is another question. We notice, however, with some regret that the guns illustrated in the text are all muzzle-loaders, as if breech-loading was the temporary fad which the rifled gun was considered in the time of the treatise of 1866.

A valuable chapter on steel, new in this edition of the treatise, reminds us that our authorities are now after thirty years' delay taking up the Whitworth method of construction of ordnance, omitting, however, the Whitworth hexagonal bore. An official Solomon gave decision in favour of Armstrong against Whitworth in their celebrated competition, with the effect of alienating the greatest steel manufacturer of the world from Government purposes. His great prototype would have encouraged now one and now the other, without committing himself to an absolute decision, and would thus have reaped for his country the benefit of the invaluable services of both competitors.

Major Mackinlay has done good service by collecting all the ballistic tables based upon the important experiments of Mr. Bashforth, and by showing how they are applied to the questions of artillery. We must be on our guard, however, against using ink instead of gunpowder, from economy, and against imagining that there is no further need of careful experiment and practice. It is of the greatest importance, too, that cadets should learn from this treatise that the science of artillery is not entirely comprised in guns of the smallest dimensions, manœuvred over rough country, and the doing of some snap shooting The history of recent wars teaches us that the field artillery of both sides is used up in the first two or three engagements, and that the conflict finally resolves itself into a vast siege, in which the whole army and navy are converted into garrison artillery.

The article by the author of "Greater Britain" in the *Fortnightly Review*, tells us of the immense pains now taken on the Continent in military preparations. Let us avoid in time the necessity of the dreary up-hill labours which the French have been compelled to undertake, now at length beginning to culminate in an organization which, it is important to keep in mind, might at any moment be tested by being brought to bear against this country.

ROMANTIC LOVE AND PERSONAL BEAUTY.

Romantic Love and Personal Beauty. By H. T. Finck. Two Vols. (London: Macmillan and Co., 1887.)

IN dealing with the subject, or, rather, the group of subjects, here indicated, Mr. Finck seems to have had before him a twofold object, scientific and practical. On the scientific side he deals with romantic love, showing (*a*) that it is a recent growth, (*b*) what are its conditions, and (*c*) what are the conditions of beauty as essential to romantic love. From a practical point of view he (*a*) gives rules for health, which is essential to beauty and therefore to romantic love, and (*b*) insists upon the necessity of free choice in love being left to young people. Let us see briefly what he has to tell us upon these points.

Goldsmith, in the "Citizen of the World," was wrong, Mr. Finck holds, in teaching that love proper existed in ancient Rome. "Romantic love is a modern sentiment, less than a thousand years old. . . . Of all personal affections the maternal was developed first, and the sentiment of romantic love last." Here Mr. Finck has certainly got hold of a truth, but he puts it much too strongly. There is nothing improbable in the growth of a new emotion, or (as we would rather say) in an old emotion receiving a new direction and a great expansion. Vol. I. (pp. 34–37) shows that parental and filial love have little or no existence among animals and among some savages; and if civilization can develop these feelings to their present pitch of intensity, it might well do the same for the mental, as distinguished from the bodily, attraction between man and woman. But the modern form of love is not a new feature; it is essentially a development. It was stunted and kept down at Rome and in most of Greece but still it was in existence; and, if Mr. Finck will extend

his classical reading, he will find more traces of it than those which he enumerates. Let him begin with the Greek novelists, and see whether Heliodorus's account of the loves of Theagenes and Chariclea will not come up to his standard.

But what are the conditions favourable to the growth of romantic love? Greece—by which Mr. Finck chiefly means Athens—was cut off from such love by three causes: the degraded position of women, the absence of direct courtship, and the impossibility of exercising individual preference (i. 126). The second and the third seem to us to run together, but still we see here some of the points on which romantic love depends; and to these may be added intellect (ii. 14), monogamy (i. 58), and a *long* courtship (i. 59). The old-fashioned plan which Goethe describes—

> "In der heroischen Zeit, da Götter und Göttinnen liebten,
> Folgte Begierde dem Blick, folgte Genuss der Begier,"—

has left us many a charming picture, and none more charming than the Homeric hymn to Aphrodite; but such prompt satisfaction of love no doubt did not give to a romantic passion sufficient time to grow. The feeling was there, but rudimentary. Now, that rudimentary feeling has so grown as to have largely pushed out of sight its physical basis, and men and women act (or think they act) upon other and higher impulses. To this change the agencies enumerated by Mr. Finck have doubtless contributed, and he would apparently acknowledge, too, that the general alteration in the position of women has affected the way in which their lovers regard them. But we should lay more stress than he does on the influence of poets and novelists; they have gone on painting unreal feelings until they have made them real; what a few characters felt at first has been worked by this agreeable sermonizing into the nature of all the readers.

But, after all, the starting-point of romantic love is beauty. Where the women are secluded, beauty cannot be seen. Where matches are made by the parents, beauty does not count. But, where free selection is left to young people, beauty takes its proper place. It is a sign of health, and "love in its primitive form urges animals to prefer those that are most healthy." Mr. Finck therefore goes on next to describe the causes which bring out beauty: "a climate tempting to outdoor life; a considerable amount of intellectual culture and æsthetic refinement; a mixture of nationalities, fusing *ethnic* peculiarities into an harmonious whole; and love, which fuses *individual* complementary qualities into an harmonious *ensemble* of beautiful features, graceful figure, amiable disposition, and refined manners" (ii. 25); or, more shortly, health, crossing, love, and mental refinement (ii. 73). Thus love and beauty act and react on each other; in connection with which point Mr. Finck makes a suggestion of some importance when he says (ii. 94-95):—

"The artificial preservation of disease and deformity, in and out of hospitals, due to Christian charity, might in the long run prove injurious to the welfare of the human race, were it not for the stepping-in of modern love as a preserver of health and beauty. What formerly was left to the agency of natural selection, is now done by love, through sexual selection, on a vast scale."

It is even more difficult to persuade women than it is to persuade men to do what is good for them, and if the close connection thus pointed out between health and beauty will not induce women to take a little trouble to preserve or improve the former, we must give them up as hopeless. By insisting on this cardinal truth, Mr. Finck will do a useful work, though some day perhaps our descendants will wonder that it should have needed insisting. There is room enough for improvement in both health and beauty. Mr. Galton tells us that "our human civilized stock is far more weakly through congenital imperfection than that of any other species of animals"; while, as for beauty, it is likely that the world is but at the beginning of what sexual selection, unhampered and unthwarted by other agencies, can do for us. It is, Mr. Finck affirms, a moral duty for girls to defy parental tyranny "where money or rank are pitted against love. For the health and happiness of the next generation are at stake."

This is strong speaking; but still, if our author would always speak as seriously and soberly as this we should have but little quarrel with him. Unfortunately he has spoiled an interesting book, not only by a gossiping and confused arrangement of its matter, but also by an intolerably jaunty style, flavoured with Americanisms. A book which claims scientific value should not be disfigured by stupid jokes (as on Prior and priority), or by such phrases as "the female persuasion," "Schopenhauer's Will is an æsthetic sort of a chap," "a young animal that would risk its own life in defence of its mother or father is yet to be heard from."

F. T. RICHARDS.

OUR BOOK SHELF.

Earth-Knowledge: A Text-book of Elementary Physiography. By W. J. Harrison, F.G.S., and H. R. Wakefield. (London: Blackie and Son, 1887.)

THIS is a small text-book adapted to the somewhat remodelled syllabus of the Science and Art Department's elementary stage of physiography. There can be no doubt about the usefulness of the book, but it is to be regretted that more originality is not displayed in the treatment of the subject of matter and energy. Of the rest of the book no complaint can be made: it is excellent. That which deals with matter and energy, however, is meagre and unequal, and the arrangement is at times unnatural. Gravitation, for instance, is discussed without any direct reference to *weight*, although two pages are devoted to the methods of determining specific gravities. Then, again, one would scarcely expect nowadays to read a chapter on *energy* without finding some mention of the doctrine of the conservation of energy.

We are afraid, also, that the chapter on voltaic electricity will be rather misleading to beginners, as no mention whatever is made of the existence of any kind of battery beyond that consisting of a single copper-zinc cell, whilst effects are described which could only be produced by the current from many such cells. The definition of a stress as the "mutual action at the surface of contact between two bodies, whereby each exerts a force upon the other," is also rather misleading, since it does not include the stresses of gravitation, electricity, and magnetism.

Of course too much cannot be expected of an elementary text-book, but it is quite time that the modern ideas regarding force, energy, and matter should be introduced into such books.

A. F.

A Dictionary of Place-Names. By C. Blackie. Third Edition, revised. (London: John Murray, 1887.)

EVERY teacher of geography knows that the derivation of place-names never fails to excite the interest of intelligent scholars. It is satisfactory, therefore, that there should have been a demand for a third edition of Mr. Blackie's excellent book, in which he presents in plain and simple language many of the most suggestive results established by students of topographical etymology. The work has been carefully revised, and in its present form ought to be of service to many a "general reader" and tourist, as well as to schoolmasters and their pupils. Prof. J. S. Blackie contributes to the volume an introductory essay, in which he offers, in his lively way, many useful hints as to the spirit in which the study of topographical etymology ought to be pursued.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

The Supposed Earthquake in England.

FROM the inquiries which have been made it is now ascertained that the loud noise—as of an explosion—heard over so wide an area on the morning of November 20, and referred to by Mr. Worthington G. Smith in your issue of last week (p. 127), was due to the breaking up of a large meteor, which crossed the north of Herts from east to west, upon a line of which the extreme points are approximately Saffron Walden, in Essex, and Swindon, in Oxfordshire. The meteor was seen by one observer from Hertford, and probably it would have been generally noticed but for the foggy state of the atmosphere. I have undertaken to investigate this matter as far as Herts is concerned, and shall be very much obliged to any of your readers who can give me assistance if they will send a note of their observations, especially as to the direction from which the shock they experienced appeared to reach them. H. GEORGE FORDHAM.

Odsey Grange, Royston, Cambridgeshire, December 12.

The "Umbria's" Wave.

IN NATURE, vol. xxxvi. (p. 508) you published some details from Mr. W. Watson about the wave which struck the *Umbria* in mid-Atlantic. Having heard of two similar cases, and being in possession of the details of one, I have made the following comparison.

Comparison of the "Umbria's" and the "Faraday's" wave.

		Umbria.	*Faraday.*
Date		26.7.87	14.2.84
Hour		4.40 a.m.	6.45 a.m.
Position of ship	Long. W.	27° 8′	27° 53′
	Lat. N.	50° 5′	46° 11′
Ship's speed—knots		about 16	about 6
Ship's course		West (probably partly South)	E. 18° N.
The wave struck		the bow	the port beam.
Probable course of wave		East partly North.	South partly East.

These two courses if prolonged backwards would intersect at about 30° W. lat. and 50° N. long. This is the very point where the *Faraday*, while laying a cable in 1882, discovered a reef rising about 6000 feet above the bed of the ocean. The *Umbria* when struck was about 120 miles to the east of this position, and the *Faraday* about twice as far to the south-east.

The *Faraday's* wave was seen fully five minutes before it struck, and then like the *Umbria's*, it did considerable damage. Three life-boats, chart-house, deck-house, and part of the bulwarks were smashed and one of the large buoys carried away.

In his letter Mr. Watson doubts whether this wave was caused by an earthquake, but a few more similar occurrences in the neighbourhood of Faraday's Reef will possibly demonstrate it to be of recent and volcanic growth. C. E. STROMEYER.

Strawberry Hill, November 22.

The Planet Mercury.

THE atmosphere in this country is generally so unfavourable that it is a very rare occurrence to see the planet Mercury even at its greatest elongation from the sun, unless carefully looked for. My experience of the last few days may therefore be worth mentioning. The day before yesterday, at 10 minutes past 7 in the morning, I was in bed at some distance from a window, through which, without directing my attention to it, I saw a star shining with sufficient brightness in the twilight to attract my notice. I raised the window and made use of a large opera-glass, when any doubt I had would have been dispelled even if I had had no previous experience of Mercury, for there was to be seen a small planet with distinct disk some 15° above the horizon—Venus, a magnificent object, being of course visible also. The same thing happened this morning, when I again noticed Mercury, without having him in my mind, before leaving my bed; but this time I was better prepared, and in the course of the next quarter of an hour had shown the planet, in a 3⅞-inch telescope, to several persons who saw it for the first time. G. F. P.

Hanworth, Middlesex, December 9.

Meteor.

ON Friday night, about 9.15, a fine meteor, as bright as a star of the first magnitude, was seen in the western sky. It made its appearance at an elevation of 35° west-south-west, and disappeared in the west, at an elevation of 20°, leaving no streak. Perhaps some other of your readers might be able to identify the meteor, and thus a clue to its course might be arrived at. If you think this worth inserting, it may interest some one.

Barrow-on-Humber, Hull, December 9. M. H. MAW.

"Fairy Rings."

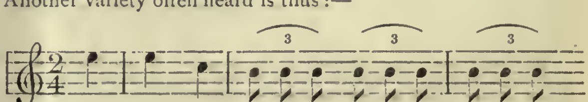
YOUR article on "Fairy Rings" (November 17, p. 61) speaks of rings of 100 feet in diameter as wholly exceptional. In the parish of Stebbing, in Essex, there is a field containing numerous rings of *Paxillus giganteus.* The largest of these is incomplete, being broken in places by gorse bushes and stopped on one side by a hedge and ditch. Measurement is consequently difficult, but the diameter of the ring cannot be less than 120 feet. At Bunchrew, in Inverness-shire, I once saw the same fungus covering about a rood of ground. The grass all over this was very coarse and dark green in colour, being chiefly *Dactylis glomerata*, but there was no trace of a ring. J. SARGEAUNT.

Felsted, December 6.

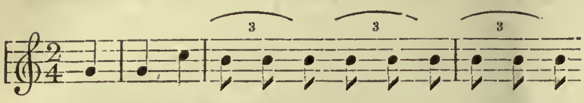
Music in Nature.

IN NATURE (vol. xxxvi. pp. 343 and 605) reference was made to melodies of birds, &c. I have often heard in the provinces of New Brunswick and Nova Scotia a bird which sings as clear and accurate a melody as can be given forth by any human songster. It is a small gray bird with double lines of velvety white on the sides of its head. I do not know its name. The song varies somewhat in different individuals, but always has the same characteristics. The commonest form is as follows:—

Another variety often heard is thus:—



A rarer form is as follows :—



I have noticed that this latter form seems more difficult for the little musicians, one of whom in particular used to provoke me by singing the B most outrageously flat. I have been accustomed to imitate these birds by whistling, and they very readily answer my whistle. In this way the different forms of their theme have become fixed in my memory. W. L. GOODWIN.

Queen's University, Kingston, Canada, November 11.

Who was Mr. Charles King?

AMONG the ingenious in many considerable parts of the world, of whose undertakings, studies, and labours the Philosophical Transactions of the years 1700 *sqq.* gave some account, an able microscopist suddenly appears, of whose life and work one would like to have more accurate information than seems to be current. Perhaps a member of the Royal, or the Royal Microscopical, Society may be able to supply some particulars about this "Anglois anonyme," as Trembley calls him, and willing to assist in rescuing his name from an undeserved oblivion. His first contribution to the Philosophical Transactions—of very little importance indeed—is to be found in No. 266, for September and October 1700, pp. 672–673, under the title, "A Letter from Mr. Charles King to Mr. Sam. Doudy, F.R.S., concerning Crabs Eyes;" it is dated, "Little Wirley, Decemb. 14," and subscribed, "Ch. King." In the copy of the Transactions I have before me, a contemporary, who seems to have been tolerably well informed, has inserted divers MS. notes, remarks, and corrections; he added here the words, "Staffordsh^{e}." to the locality, and "Student of Ch. Ch. Oxon." to the subscription, which, as far as I know, does not recur in any of the subsequent Transactions. But under the title, "Two Letters from a Gentleman in the Country, relating to Mr. Leuwenhoeck's Letter in Transaction, No. 283, Communicated by Mr. C." (in No. 288, for November and December 1703, pp. 1494–1501, with eight figures, text and illustrations being both equally remarkable for the period), the same hand has again inscribed the name of "Mr. Charles King," and filled up the blanks left on pages 1494 and 1495 by the initials "W." and "W. Ch. Esq." with the additions of "irley par. Cōm. Stafford." and "Walter Chetw... of Ingestry Staffords^{e}." (the rest has been cut off by the binder of the volume), so that there remains no reasonable doubt as to the truth of the identification. Now we read in the second of these letters from the country, dated "July 5, 1703," p. 1501, "But of those" (viz. animalcula) "(among other things) I last year gave an account to Sir Ch. Holt, which I hear will shortly be publish'd in the Transactions." I don't think it is bold to conjecture that the account here alluded to had already been published, and is, in fact, the article printed in No. 284, for March and April 1703, pp. 1357(*bis*)–1372 (with excellent figures on the plate accompanying that number), under the title of "An Extract of some Letters sent to Sir C. H. relating to some Microspocal" (*sic*) "Observations. Communicated by Sir C. H. to the Publisher" (H. Sloane); and no doubt these epistles may also be ascribed to the same anonymous gentleman.

In all the above-mentioned letters we have some early and first-rate contributions to microscopical science, the importance of which had been shortly before so evidently demonstrated by the wonderful discoveries made by the improved magnifying-glasses.

Quæritur: Who was Mr. Charles King? S.

The Hague, November 27.

NOTE ON A PROPOSED ADDITION TO THE VOCABULARY OF ORDINARY ARITHMETIC.[1]

THE total number of distinct primes which divide a given number I call its Manifoldness or Multiplicity.

[1] Perhaps I may without immodesty lay claim to the appellation of the Mathematical Adam, as I believe that I have given more names (passed into general circulation) to the creatures of the mathematical reason than all the other mathematicians of the age combined.

A number whose Manifoldness is n I call an n-fold number. It may also be called an n-ary number, and for $n = 1, 2, 3, 4, \ldots$ a unitary (or primary), a binary, a ternary, a quaternary, ... number. Its prime divisors I call the *elements* of a number; the highest powers of these elements which divide a number its *components;* the degrees of these powers its *indices;* so that the indices of a number are the totality of the indices of its several components. Thus, we may say, a prime is a one-fold number whose index is unity.

So, too, we may say that all the components but one of an odd perfect number must have even indices, and that the excepted one must have its base and index each of them congruous to 1 to modulus 4.

Again, a remarkable theorem of Euler, contained in a memoir relating to the Divisors of Numbers ("Opuscula Minora," vol. ii. p. 514), may be expressed by saying that *every even perfect number is a two-fold number, one of whose* components *is a prime, and such that when augmented by unity it becomes a power of* 2, *and double the other component.*[1]

Euler's function $\phi(n)$, which means the number of numbers not exceeding n and prime to it, I call the *totient* of n; and in the new nomenclature we may enunciate that *the totient of a number is equal to the product of that number multiplied by the several excesses of unity above the reciprocals of its elements.* The numbers prime to a number and less than it, I call its *totitives.*

Thus we may express Wilson's generalized theorem by saying that any number is contained as a factor in the product of its totitives increased by unity if it is the number 4, or a prime, or the double of a prime, and diminished by unity in every other case.

I am in the habit of representing the totient of n by the symbol $\tau n, \tau$ (taken from the initial of the word it denotes)

[1] It may be well to recall that a perfect number is one which is the half of the sum of its divisors. The converse of the theorem in the text, viz. that $2^n(2^{n+1} - 1)$, when $2^{n+1} - 1$ is a prime, is a perfect number, is enunciated and proved by Euclid in the 36th (the last proposition) of the 9th Book of the "Elements," the second factor being expressed by him in the sum of a geometric series whose first term is unity and the common ratio 2. In Isaac Barrow's English translation, published in 1660, the enunciation is as follows:—"If from a unite be taken how many numbers soever 1, A, B, C, D, in double proportion continually, untill the whole added together E be a prime number; and if this whole E multiplying the last produce a number F, that which is produced F shall be a perfect number."

The direct theorem that every even perfect number is of the above form could probably only have been proved with extreme difficulty, if at all, by the resources of Greek Arithmetic. Euler's proof is not very easy to follow in his own words, but is substantially as follows:

Suppose P (an even perfect number) $= 2^n A$. Then, using in general $\int X$ to denote the sum of the divisors of X,

$$2 = \frac{\int P}{P} = \frac{\int 2^n \cdot \int A}{2^n A} = \frac{2^{n+1} - 1}{2^n} \cdot \frac{\int A}{A}.$$

Hence $$\frac{\int A}{A} = \frac{2^{n+1}}{2^{n+1} - 1}, \text{ say } = \frac{Q+1}{Q}.$$

Hence $A = \mu Q$, and $\int A = 1 + \mu + Q + \mu Q + \ldots$ (if μ be supposed > 1). Hence unless $\mu = 1$ and at the same time Q is a prime

$$\int A > \mu(Q + 1),$$

i.e. $\dfrac{\int A}{A}$ is greater than itself.

Hence an even number P cannot be a perfect number if it is not of the form $2^n(2^{n+1} - 1)$, where $2^{n+1} - 1$ is a prime, which of course implies that $n + 1$ must itself be a prime.

It is remarkable that Euler makes no reference to Euclid in proving his own theorem. It must always stand to the credit of the Greek geometers that they succeeded in discovering a class of perfect numbers which in all probability are the only numbers which are perfect. Reference is made to *so-called* perfect numbers in Plato's "Republic." H, 546 B, and also by Aristotle, Probl. I E 3 and "Metaph." A 5, which he attributes to Pythagoras, but which are purely fanciful and entitled to no more serious consideration than the late Dr. Cummings's ingenious speculations on the number of the Beast. Mr. Margoliouth has pointed out to me that Muhamad Al-Sharastani, in his "Book of Religious and Philosophical Sects," Careton, 1856, p. 267 of the Arabic text, assigns reasons for regarding all the numbers up to 10 inclusive as perfect numbers. My particular attention was called to perfect numbers by a letter from Mr. Christie, dated from "Carlton, Selby," containing some inquiries relative to the subject.

being a less hackneyed letter than Euler's ϕ, which has no claim to preference over any other letter of the Greek alphabet, but rather the reverse.

It is easy to prove that the half of any perfect number must exceed in magnitude its totient.

Hence, since $\frac{3}{2} \cdot \frac{5}{4}$ is less than 2, it follows that no odd two-fold perfect number exists.

Similarly, the fact of $\frac{3}{2} \cdot \frac{7}{6} \cdot \frac{11}{10}$ being less than 2 is sufficient to show that 3, 5 must be the two least elements of any three-fold perfect number; furthermore, $\frac{3}{2} \cdot \frac{5}{4} \cdot \frac{17}{16}$ being less than 2, shows that 11 or 13 must be the third element of any such number if it exists[1]—each of which hypotheses admits of an easy disproof. But to disprove the existence of a four-fold perfect number by my actual method makes a somewhat long and intricate, but still highly interesting, investigation of a multitude of special cases. I hope, *numine favente*, sooner or later to discover a general principle which may serve as a key to a universal proof of the non-existence of any other than the Euclidean perfect numbers, for a prolonged meditation on the subject has satisfied me that the existence of any one such—its escape, so to say, from the complex web of conditions which hem it in on all sides—would be little short of a miracle. Thus then there seems every reason to believe that Euclid's perfect numbers are the only perfect numbers which exist!

In the higher theory of congruences (see Serret's "Cours d'Algèbre Supérieure") there is frequent occasion to speak of "a number n which does not contain any prime factor other than those which are contained in another number M."

In the new nomenclature n would be defined as *a number whose elements are all of them elements of* M.

As τN is used to denote the totient of N, so we may use μN to denote its multiplicity, and then a well-known theorem in congruences may be expressed as follows.

The number of solutions of the congruence

$$x^2 - 1 \equiv 0 \pmod{P}$$

is $2^{\mu P}$ if P is odd,

$2^{\mu P - 1}$ if P is the double of an odd number,

$2^{\mu P}$ if P is the quadruple of an odd number,

and $2^{\mu P + 1}$ in every other case.

In the memoir above referred to, Euler says that no one has demonstrated whether or not any odd perfect numbers exist. I have found a method for determining what (if any) odd perfect numbers exist of any specified order of manifoldness. Thus, *e.g.*, I have proved that there exist no perfect odd numbers of the 1st, 2nd, 3rd, or 4th orders of manifoldness, or in other words, no odd primary, binary, ternary, or quaternary number can be a perfect number. Had any such existed, my method must infallibly have dragged each of them to light.[2]

In connection with the theory of perfect numbers I have found it useful to denote $p^i - 1$ when p and i are left general as the Fermatian function, and when p and i have specific values as the ith Fermatian of p. In such case p may be called the base, and i the index of the Fermatian.

[1] 3, 5, 7 can never co-exist as elements in *any* perfect number as shown by the fact that $\frac{1+3+3^2}{9} \cdot \frac{1+5}{5} \cdot \frac{1+7+49}{49}$; *i.e.* $\frac{26}{15}\left(1 + \frac{1}{7} + \frac{1}{49}\right)$ is *greater* than 2. Thus we see that no perfect number can be a multiple of 105. So again the fact that $\frac{5}{4} \cdot \frac{7}{6} \cdot \frac{11}{10} \cdot \frac{13}{12} \cdot \frac{17}{16} \cdot \frac{19}{18}$ is *less* than 2 is sufficient to prove that any odd perfect number of multiplicity less than 7 must be divisible by 3.

[2] I have, since the above was in print, extended the proof to quinary numbers, and anticipate no difficulty in doing so for numbers of higher degrees of multiplicity, so that it is to be hoped that the way is now paved towards obtaining a general proof of this *palmary* theorem.

Then we may express Fermat's theorem by saying that *either the Fermatian itself whose index is one unit below a given prime or else its base must be divisible by that prime.*[1]

It is also convenient to speak of a Fermatian divided by the excess of its base above unity as a Reduced Fermatian and of that excess itself as the Reducing Factor.

The spirit of my actual method of disproving the existence of odd perfect numbers consists in showing that an n-fold perfect number must have more than n elements, which is absurd. The chief instruments of the investigation are the two inequalities to which the elements of any perfect number must be subject and the properties of the prime divisors of a Reduced Fermatian with an odd prime index.

New College, November 28. J. J. SYLVESTER.

[1] So too we may state the important theorem that if *an element of a Fermatian is its index the component which has that index for its base must be its square.*

COUTTS TROTTER.

A GREAT calamity has fallen on the University of Cambridge and on Trinity College, and many men differing widely in their interests and callings are bearing together the burden of a common sorrow in the knowledge that the Rev. Coutts Trotter, the Vice-Master of Trinity College, was no more. Mr. Trotter suffered from a severe and prolonged illness during last winter and early spring, and though in the summer he seemed to have almost regained his health, he began as the year advanced once more to lose ground. When he returned from abroad in October his condition gave rise to great anxiety among his friends; as the term went on he grew worse rather than better; and an attack of inflammation of the lungs rapidly brought about the end, which took place in his rooms in College, in the early morning of Sunday, December 4.

During the last twenty of the fifty years of Mr. Trotter's life both the University of Cambridge and Trinity College have undergone great and important changes. In bringing about these changes Mr. Trotter had a great share, perhaps a greater share than any other individual member of the University; and while those changes are probably neither wholly good nor wholly evil, but good mixed with evil, no one hand, as the changes were being wrought, did so much good and so little evil as his. A wide and yet accurate knowledge of many different branches of learning, a genuine sympathy with both science and scholarship, a judicial habit of mind which enabled him to keep in view at the same time broad issues and intricate details, a clear insight into the strength and weakness of academic organization, and a singular skill in drafting formal regulations,—these qualities, aided by a kindly courtesy which disarmed opponents, and a patience which nothing except perhaps coarse rudeness could ruffle, enabled him in his all too short life to do for his College and for his University more than it seemed possible for one man to do.

The academic labours which thus year by year increased upon him, though they in many ways, both directly and indirectly, tended to the advancement of science, became, increasingly, hindrances to his pursuing actively any special path of scientific inquiry, as he had once hoped to do. His love of science began with his boyhood, while he listened to the Royal Institution lectures of Faraday. Having taken a degree, with honours in both classics and mathematics, and having obtained a Fellowship at Trinity, he gave up to scientific study much of the leisure thus afforded to him; and, in order more thoroughly to train himself, spent the best part of two years at Heidelberg, during a portion of which time he was engaged in physiological research under Helmholtz. He acquired a very

considerable knowledge of chemistry and botany, but afterwards confined his attention more especially to physics, and lectured experimentally on this subject for several years in Trinity College. In his earlier days he was an enthusiastic Alpine climber, and this led him to direct his knowledge of physics towards the solution of glacial problems. He commenced a few years ago, in the ice-caves of Grindelwald, a series of observations on the physical properties of ice, some of the initial results of which were communicated to the Royal Society. He was never able, however, to continue, much less to complete, these observations, and perhaps the cruellest feature to him of his illness last winter was that it prevented him from spending the Christmas vacation at Grindelwald, as he had hoped to do, in carrying on measurements of ice, under the most natural conditions, in the depths of an ice-cave.

But the gain to science from Trotter's life is not to be measured by his formal contributions to scientific literature. He had a great unwillingness to write "papers." Though he served for several years as one of the secretaries, and at the time of his death was President, in the second year of office, of the Cambridge Philosophical Society, whose very life consists in scientific research, and though in the discussions at the meetings he frequently made his critical power felt, his name does not often appear in the Society's publications. He was especially interested in physiological optics, but, though he made many observations, was always disinclined to commit his results to paper. His real scientific usefulness is to be seen in his University and College work. The recent development of natural science (other than mathematical) at Cambridge is coincident in time with, and in great measure due to, Trotter's academic activity.

In the encouragement given at Trinity to natural science, in all the changes of University ordinances tending to encourage scientific research, and to place the teaching of science on a broader and firmer basis, it is easy to trace his hand. He did not always have his own way, and often thought it prudent to accept an arrangement the shortcomings of which he clearly saw; but his influence, becoming more and more powerful year by year, was always exerted to promote the growth of science in the University, for he at least had no doubt that he was thus working for the welfare both of the University and of his College. He had such a firm grasp of the dominant ideas, and was so wholly in touch with the spirit, of almost every one of the various branches of science, that each teacher and worker sought his help and trusted in his counsel. On the other hand, his conspicuous sympathy with literature and art enabled him to win from those who were strangers to science an assent which would have been denied to claims advocated by others. Happily, too, his singularly catholic mind and temper were made still more potent by a remarkable skill in handling details and conducting business. Were Maxwell now alive, he would be able to tell, as Rayleigh and Thomson can tell, how great a help Trotter was to the Cavendish Laboratory and to physics. The Regius Professor of Physic knows how often Trotter's great knowledge of the needs of medicine on the one hand, and of the capabilities of academic organization on the other, as well as his legislative ability, were of signal service in the difficult deliberations of the Board of Medical Studies. Liveing can say how much not only the very existence, but the details of construction, of the new Chemical Laboratory are due to Trotter's co-operation with himself, and Stuart will tell a like story about the Engineering School. Each science in turn brought its wants to Trotter, and seldom brought them in vain. He recognized Frank Balfour's powers as early as I did, and did more for him in his College and in the University than I could do. All my younger friends whom I am proud to think of as once my pupils, who are making their names known in physiology, in morphology, and in botany, have always looked up to him as a friend who never failed. And, as for myself, whatever I may have done at Cambridge has been done from first to last through him, and could not have been done without him: in him I have lost my oldest, truest, best helpmate.

I first came to know him a year or so before I received my appointment at Trinity College. Happening to pay a visit to Prof. Humphry, I was taken by him to call on "a young Fellow of Trinity interested in science, and especially in physiology, a capital fellow!" That "young Fellow" was Trotter. I saw, even in our brief interview, much in him to draw me to him, and he seemed to see something of the same kind in me, so that when, a year after, a sudden change in all my plans placed me within the walls of Trinity, he and I began a friendship which has ceased only with his death. All through the thirteen years during which, while working within the University, I was really outside the University, my every movement was made by and through Trotter; and since I have been Professor my every movement has been made with him. For seventeen years I have been able to make him a partner in my plans; he has shared in my hopes and soothed me in my failures; where I have been successful he has helped, and when I have refused or neglected his counsel I have generally gone wrong. When Balfour was taken I could feel that Trotter was left, and now he is gone too.

But I ought not to thrust these personal matters on the readers of NATURE, and indeed, great as my own loss is, that of Trinity College and of the University is far greater. Those who know the University and knew Trotter will feel at once how great a blow is his death at the present juncture. The University, both in its scientific and in its other work, is straitened for lack of funds: laboratories cannot be built, teachers cannot be adequately paid, research cannot be properly encouraged, because the necessary money is not at hand. At the same time the revenues of the several Colleges are suffering acutely from the depreciation in the value of land, and a movement has been set on foot with the view of diminishing the contributions of the Colleges to the University. If this movement is successful—and its success seems assured by the fact that the new Member for the University has, in his address to the electors, given a conspicuous pledge that he, with his commanding scientific authority, will support it in Parliament—it will need the wisest and most skilful handling of details to prevent the result proving disastrous to the cause of learning, and especially of scientific learning, in the University. So long as Trotter was alive we felt that we had one in whom devotion to his College was no less strong than his love for the University and for learning, and we looked to him as the man who, trusted alike by the Colleges and by the University, would be found to have skill to steer us in the difficult way before us. Now, in the darkness of his death, we seem to be driving, without a pilot, straight upon the rocks.

M. FOSTER.

H. C. F. C. SCHJELLERUP.

THE Danish astronomer Prof. Hans Carl Frederick Christian Schjellerup died at the Copenhagen Observatory on November 13 after a prolonged illness. He was born on February 8, 1827, at Odense, where his father was a jeweller, and was apprenticed to a watchmaker, but by private study he succeeded in supplementing the education he had received in his native town so well that he was able to pass the entrance examination at the Polytechnic School of Copenhagen in 1848. Here he distinguished himself by his mathematical ability, and was able to finish his studies in the course of two years, when he passed the final examination in applied mathematics and mechanics. In 1851 he

was appointed observer in the old Observatory at Copenhagen, which had been built at the time of Longomontanus, on the top of a high tower, and was therefore, after the lapse of two centuries, greatly behind the times, both as to locality and instruments. A few years afterwards he was appointed Professor of Mathematics at the Naval Academy, and Instructor in Geometrical Drawing at the Polytechnic School. These appointments he retained till the time of his death, as well as his position at the Observatory, and though he was in 1875, after the death of Prof. D'Arrest, strongly urged by the Minister of Public Instruction to allow himself to be appointed Professor of Astronomy, he preferred remaining as he was, partly owing to the pecuniary loss the change would have entailed, partly because his scientific activity was untrammelled by routine duties, and left him leisure to pursue his studies in whatever direction he chose.

As long as Schjellerup had only at his disposal the instruments of the old Observatory, he chiefly occupied himself with the computation of orbits of planets and comets, among which his determination of the orbit of the comet of 1580 deserves to be specially mentioned. This was founded on a complete reduction of Tycho Brahe's original observations of the distance of the comet from stars, and of his time determinations by altitudes and azimuths of standard stars. In 1861 the new Observatory was finished, and furnished with an 11-inch refractor by Merz and a transit-circle by Pistor and Martins. With the latter Schjellerup commenced in September 1861 to observe zones of stars, chiefly of the eighth and ninth magnitudes, between $+15^\circ$ and -15° declination, and already in the beginning of December 1863 he had finished the observation of ten thousand stars, while the reductions had been pushed on with so much energy that the complete catalogue of mean places for 1865 was laid before the Royal Danish Society of Science a month after. When it is remembered that the author of this work during the greater part of the year had to spend three or four hours a day in teaching, it will be conceded that he made good use of his time. The star catalogue is so well known for its fulness and accuracy that it is unneccessary to dwell further on it in this place. After its completion, Schjellerup intended, and had already commenced, to continue the observations north of the limit of $+15^\circ$, as Bessel had done forty years before, but about this time his interests took a new direction, which made him discontinue systematic observations, while he may also have been influenced by the circumstance that the great undertaking of the Astronomische Gesellschaft, viz. the observing of all stars in the northern hemisphere down to the ninth magnitude, had just then been planned, whereby zone work on Lalande's plan became of less importance.

Schjellerup now with his usual energy threw himself into the study of Oriental languages, especially Arabic and Chinese. In the Royal Library of Copenhagen he found a manuscript of the description of the heavens by the Persian astronomer Abd-al-Rahman al-Sûfi, a work which up to that time had been very little known among astronomers. Finding that it contained a complete and careful uranometry from the tenth century, or in other words from an epoch nearly equidistant between Ptolemy and Argelander, he resolved to translate it and was fortunate enough to obtain the use of another manuscript from the Imperial Library of St. Petersburg. The work was published in 1874 by the Academy of St. Petersburg under the title, "Description des étoiles fixes composée au milieu du dixième siècle de notre ère par l'astronome Persan Abd-al-Rahman al-Sûfi." It has been found most valuable by the astronomers who of late years have studied the relative brilliancy of the fixed stars, and Sûfi's results have been systematically collated with their own by Messrs. Peirce, Pritchard, and Pickering.

The great value which this old work was found to possess for modern research induced Schjellerup to endeavour to make other observations of the ancient astronomers fruitful for the investigations of the present day. To the journal *Copernicus* he contributed three papers under the common title, "Recherches sur l'Astronomie des Anciens." The first shows that the time stars of Hipparchus had been so well selected that their culminations gave the correct time every hour of the night within a minute, the second discusses the Chinese observations of the total eclipses of the years −708, −600, and −548, while the third compares seven conjunctions of the moon with fixed stars recorded by Ptolemy, with Hansen's lunar tables. He further examined the occultations and conjunctions of planets observed by the Greek astronomers, and the principal eclipses of the Middle Ages, but these investigations appear to have been left unfinished at his death.

Among Schjellerup's minor publications should be mentioned his catalogue of red stars (first published in 1866, and in a revised edition in 1874), which appeared most opportunely at a time when the spectroscope had just commenced to be applied to the study of the physical constitution of the stars.

In addition to being a man of very extensive knowledge, both scientific and general, Schjellerup was a kind teacher and friend, always willing to assist with his vast store of learning anybody who consulted him. His memory will be gratefully cherished by those who had the good fortune to know him. J. L. E. DREYER.

NOTES.

DR. ASA GRAY, we are sorry to learn, has been stricken with apoplexy at his house in Cambridge, Massachusetts.

SIR GEORGE BURROWS, F.R.S., died on Monday. He was in his eighty-seventh year.

WE regret to have to announce the death, at the early age of thirty-four, of Prof. Humpidge, of the University College of Wales. Dr. Humpidge was educated at the Grammar School, Gloucester, was for some years in trade, and in spare time student in science classes, where he obtained a silver medal in geology from the Department. He afterwards studied at the School of Mines, and obtained one of the three Jodrell Scholarships. In the examination for B.Sc. at the London University he obtained the second place in the honours list, and the two years' £40 scholarship. After studying with Bunsen at Heidelberg, and teaching at Hofwyl in Berne, he was appointed in 1879 to the chemistry class at Aberystwith. At Kensington Dr. Humpidge carried on some researches on the coal-gas of the metropolis, under Prof. Frankland, and in Heidelberg he took up the study of the rare metals yttrium, erbium, and beryllium, results of which were published in the Journal of the Chemical Society, Philosophical Transactions, and Proceedings of the Royal Society. His later work was the preparation of several rare metals in a state of purity for the determination of their specific heats in his calorimeter. The fire which unfortunately destroyed the College in the summer of 1885 caused irreparable loss to Dr. Humpidge, all his papers and results and chemicals being burnt, and he had also a very narrow escape from the flames in endeavouring to rescue people and property. The shock of this accident undermined his health, and although he continued to teach in temporary premises for some time he was finally obliged to visit the South of Europe for a winter, but the relief was only temporary, and he succumbed, after three weeks of great suffering, on November 30. Dr. Humpidge translated Kolbe's "Inorganic Chemistry," which has reached its second edition. Unfortunately his long illness ran away with any provision

that may have been made for his wife and family (two children of three and five years), and their sad condition calls for the consideration of his scientific colleagues.

IN opening the exhibition, at the People's Palace, of the work of London apprentices, on Saturday, the Prince of Wales delivered an excellent speech on technical education. He was able to announce that, thanks to the generosity of the Drapers' Company and the Charity Commissioners, the People's Palace will soon be on a permanent footing. He also stated that the Ironmongers' Company and the Charity Commissioners are to co-operate for the establishment, in some other part of London, of an institution corresponding to the People's Palace—an institution for providing technical, scientific, commercial, and artistic education united with physical and social recreation.

A COMMITTEE, consisting for the most part of members of the two Commissions which presided over the Prehistoric and Ethnographic Sections in the Paris Exhibition of 1878, has been appointed by the French Minister of Commerce and Industry to preside over Section I. of Technological History at the Exhibition of 1889. This department, which will be located in the so-called Palais des Arts libéraux, will represent physical, or technical, anthropology, prehistoric archæology, and ethnography. The four other Sections connected with anthropological and ethnographic sciences will respectively illustrate the liberal arts, arts and trades, means of transport, and military arts. The President of the Committee is M. de Rozière, and the Acting Secretary M. P. Topinard, editor of the *Revue d'Anthropologie*, through whose pages an appeal is made to foreign as well as French anthropologists for contributions to this Section of the coming Exhibition, such, more especially, as casts of skulls and other parts of the body by which racial types can be best illustrated.

THE Chief Signal Officer of the United States has issued his Report for the fiscal year ending June 30, 1887. The Report shows that there has been a growing demand for weather forecasts: as a rule, predictions are made for forty different districts. The system of cold-wave warnings continues in successful operation: these warnings imply that the temperature will fall below 45°, and that in twenty-four hours an abnormal fall of 15° or more will occur. Such predictions are valuable both as regards agricultural interests and personal comfort. A bulletin showing the effect of the weather for the previous seven days on important growing crops is now issued once a week. The State services play an important part in the meteorological organizations of the United States. These now number nineteen, in addition to the New England Meteorological Society. It is recommended that the attention of Congress be called to the propriety of making an appropriation for the service of telegrams now sent from the United States to Europe, in view of their importance to ship-masters of all countries.

AT the meeting of the French Meteorological Society, on November 9, attention was drawn to the establishment of a meteorological station at Bagnères-de-Bigorre. This station is of importance from its position at the foot of the Pic-du-Midi, being about 7540 feet below the mountain observatory. M. Teisserenc de Bort submitted an atlas of maritime meteorology, which has just been published with the co-operation of the Central Meteorological Office of France.

ON November 16, Dr. Buys Ballot, Director of the Royal Meteorological Institute of the Netherlands, was presented with a gold medal, at a banquet held in his honour, as a mark of respect on his completion of forty years of eminent services (1847–87). The meeting was attended by men of science from various countries.

Ciel et Terre of November 1 discusses an investigation of the surface temperature of the ocean, by Prof. O. Krümmel, in the *Zeitschrift für Wissenschaftliche Geographie*, containing charts for February and August, with coloured isotherms for each 2° C., over all oceans. The space occupied in latitude by water of 75° F. is calculated for the Atlantic and Pacific Oceans. Temperatures above 86° F. are found only at isolated points, as on the west coast of Central America, in August. Nearly 40 per cent. of the whole superficies of the ocean, both in February and August, has a temperature above 75°. The low temperature on the west coasts of Africa and South America is attributed by the author to the action of the winds instead of to the action of Polar surface currents, by which it has hitherto been explained.

DURING last autumn the German Fishery Association despatched the steamer *Holsatia* into the Baltic for scientific research, some of the results of which have just been made public. There were on board Prof. Hensen, Dr. Brandt, Dr. Oldenburg, and several officials connected with the German fisheries. The *Holsatia* left Memel on September 14, and, steering in a north-westerly direction, trawled over her course in order to ascertain what fish were most plentiful at that season. This proved to be herring. In the deep channel running to the north-west of Memel, between that city and the Hoberg bank, off the island of Gottland, it was found that the temperature of the sea, at a depth of 142 metres only, was 3° C., whereas at the surface it was 14° C. Several measurements were taken, but with the same result. This spot being one of the deepest in the Baltic, it has been suggested that this abnormal temperature may be caused by some cold under-current coming from the Gulf of Bothnia or the Bay of Finland. From this point the course was shaped for the island of Öland and the fishing-bank called "Mittelbank," soundings being taken throughout. Net-fishing was also carried on, particularly with a so-called "vertical" net, employed for the purpose of ascertaining the nature of the food of fish in certain waters. Some trawling resulted in the bringing up of boulders of a very curious shape, as well as mussels and other marine animals. All the objects brought up were photographed.

IN the December Bulletin of Miscellaneous Information, issued from the Royal Gardens, Kew, there is an interesting account of cubebs, the value of which has risen rapidly during the last few years. There are also excellent papers on Sabicu wood, Mexican fibre or istle, the food-grains of India, broom root or Mexican whisk, Contrayerva, the introduction of the Brazil nut to the East Indies and Australia, and the Castilloa rubber of Central America.

ANOTHER comprehensive application of the well-known reaction of Messrs. Friedel and Crafts, which has played so remarkable a *rôle* in organic chemistry, has recently been made by M. Léon Roux. In a long but highly interesting communication to the *Annales de Chimie et Physique*, M. Roux describes how he has been enabled, with the aid of that wonderful substance, chloride of aluminium, to extend the bounds of chemistry still further, by preparing a large number of higher homologues of naphthalene. In fact, he has been successful in building up from the heavier molecule of naphthalene an entirely new series of hydrocarbons, analogous in many respects to the series derived, by the earlier use of this reaction, from the lighter molecule of benzene. The insertion of the CH_3 groups, however, is a much more difficult operation in the naphthalene than in the benzene series, and requires a much higher temperature; the homologues themselves, moreover, are much more interesting, inasmuch as two isomeric kinds, α and β, of each are possible. Thus the methyl naphthalene $C_{10}H_7 . CH_3$ formed by the new method was found to consist of a mixture of the α and β isomers, which could be partially separated by taking advantage of

their different points of solidification. Ethyl naphthalene, $C_{10}H_7 . C_2H_5$, was most readily obtained by warming, in a flask connected with an inverted condenser, a mixture of 200 grammes naphthalene, 200 grammes ethyl iodide, and 20 grammes of aluminium chloride, added gradually as the reaction proceeded. The fraction of the product boiling between 249° and 254° was isolated as a colourless highly refractive liquid, exhibiting violet fluorescence, and was shown by analysis, and by the nature of its oxidation products, to consist of almost pure β ethyl naphthalene mixed with a minute quantity of the α compound. In a similar manner, propyl, butyl, amyl, and benzyl naphthalene have been prepared; indeed, there appears to be no limit to the number of naphthalene derivatives possible to be obtained in this manner, and there can be no doubt that M. Roux is perfectly warranted in applying the somewhat exclusive term "classical" to the work of Messrs. Friedel and Crafts, which has led to the synthesis of so large a number of carbon compounds.

AT the meeting of the Helvetic Society of Sciences this year Prof. Weber described a very sensitive micro-radiometer made in the following way:—One arm of a Wheatstone's bridge is formed by a thin tube, which is filled in its middle part with mercury, and at its ends, for about 5 mm., with a solution of zinc sulphate. To each end of the tube is fitted a metallic case, one side of which consists of a plate of rock salt. This case is filled with air, which dilates under the influence of radiation forces back the zinc-sulphate solution in the tube, and thus greatly increases the electric resistance on that side. The apparatus is made symmetrical, to eliminate variations of temperature and pressure. This radiometer will indicate 100-millionths of a degree. The moon's radiation gives a galvanometric oscillation of about five divisions.

IT is estimated that the air in a room becomes distinctly bad for health when its carbonic acid exceeds 1 part in 1000. An apparatus has been recently patented by Prof. Wolpert, of Nürnberg, which affords a measure of the carbonic acid present. From a vessel containing a red liquid (soda-solution with phenolphthalein) there comes every 100 seconds, through a siphon-arrangement, a red drop on a prepared white thread about a foot and a half long, and trickles down this. Behind the thread is a scale beginning with "pure air" (up to 0·7 per 1000) at the bottom, and ending above with "extremely bad" (4 to 7 per 1000 and more). In pure air the drop continues red down to the bottom, but it loses its colour by the action of carbonic acid, and the sooner the more there is of that gas present.

SOME interesting experiments on the reciprocal influence of organs of sense have been recently made by Herr Urbanschitsch, of Vienna. His general conclusion is that any sense-excitation has for result an increase of the acuteness of other senses. Thus, sensations of hearing sharpen the visual perceptions. If coloured plates are placed at such a distance that one can hardly distinguish the colours, and various sounds are then produced, the colours become generally more distinct the higher the sounds. Similarly, one can, while a sound affects the ear, read words which one could not read before. Again, the ticking of a watch is better heard when the eyes are open than when they are closed. Red and green increase auditive perceptions; but blue and yellow weaken them. Several musicians, however, were agreed that red, green, yellow, and blue caused an intensification of sound about one-eighth; while violet had a weakening effect. Taste, smell, and touch are under like laws. Light, and red and green colour, increase their delicacy; while darkness, blue, and yellow diminish it. Under the influence of red and green, taste extends from the anterior border of the tongue to the whole surface. On the other hand, a strengthening of smell, taste, or touch, exalts the other sensitive perceptions. Specially interesting is the reciprocal influence of touch and the sense of temperature. If one tickle the skin with a hair, and plunge the hand in hot water, the tickling sensation ceases; on the contrary, if the hand be placed in cold water, and a part of the body tickled, the temperature is felt more vividly. Herr Urbanschitsch finds in this reciprocal action an explanation of supposed double consecutive sensations on excitation of one sense.

PROF. LINDEMAN contributes to the last two issues of the *Bulletin de la Société des Naturalistes de Moscou* (1887, Nos. 2 and 3) two very elaborate papers on the Hessian fly. He points out that there can be no universal remedies for this pest, because the manner of life of the Hessian fly, and the conditions of its multiplication, vary to some extent in different climates. His study of the Hessian fly in the neighbourhood of Moscow has enabled him to describe at length the conditions which are, and those which are not, favourable for its development in that district. About Moscow it never propagates on any of those plants —Gramineæ or others—which grow amidst the crops of the Russian corn-fields. Of the three generations which develop there—the spring generation, from the beginning of May to the beginning of June (old style), the summer one, from June 19 to the beginning of August, and the autumn one, to the end of August—each must find for its propagation green stems of rye, wheat, or barley; and these stems must remain green and succulent throughout the twenty-eight days that the larva is living. Of insects which hunt the larvæ of the Hessian fly, *Geophilus*, the larva of a *Cantharid*, and one mite are noticed. The parasitic Pteromalines of the fly have been described by the same author in the first number of this year's *Bulletin*.

WE have received the last number of the Transactions of the Asiatic Society of Japan (vol. xv. Part 1), in which the well-known Chinese scholar Mr. E. H. Parker discusses in two papers the relation between the Japanese language and the languages of the neighbouring continent. He comes to the conclusion, after an elaborate examination of a list of a thousand Japanese words, that a great part of the modern Japanese language may be traced back to a language common with that language from which the modern dialects of China have all been derived. Mr. Walter Dening gives an abstract of the rules, an account of the general work, and a list of the papers published in the Proceedings of a Japanese Society established for the discussion and elucidation of various educational questions; or, in the words of its rules, "to raise the standard of scholarship and supply the wants of the teacher and reformer." Amongst the papers which have been published by the Society we select the titles of a few in order to show its scope:—"Female Education"; "An Account of the Origin and Development of Natural History in Japan"; "The Compilation of a Japanese Grammar"; "On Sending Students of Natural History to China and Corea"; "The Connection of Clothing and Health"; "Iron Ore"; "The Origin of Certain Customs"; "The Five Races of China." So far, eight parts of the Society's magazine appear to have been published, and these contain about a hundred papers by Japanese scholars of eminence, many of them, like Ito Keisuke, the veteran botanist, bearing names known in Europe.

WE have received Nos. 31–45 of "Länderkunde des Erdteils Europa," a valuable and most interesting work, edited by Prof. Alfred Kirchhoff, which is being issued in "Lieferungen." Prof. Kirchhoff is aided by many eminent writers. The publishers are F. Tempsky, of Vienna and Prague, and G. Freytag, of Leipzig.

TWO papers just printed in the Philosophical Transactions of the Royal Society have been sent to us—"Some Anomalies in the Winds of Northern India, and their Relation to the Distribution of Barometric Pressure," by S. A. Hill; and "Studies on some New Micro-organisms obtained from Air," by Grace C. Frankland and Percy F. Frankland.

MR. F. MOORE, having completed the "Lepidoptera of Ceylon," has now in preparation a much more extensive work comprising the Lepidopterous insects of the entire Indian region. It will be issued in monthly parts, to subscribers only, by the publishers of his previous work, Messrs. L. Reeve and Co.

MR. H. T. OMMANEY, C.S., of Karwar, has sent to the Bombay Natural History Society a full-grown live specimen of the Hamadryad, or King Cobra (*Ophiophagus elaps*). The reptile, which measures about 12 feet in length, is jet black, with faint cream-coloured bars across its back. The throat is of a golden-yellow colour.

A NEW "Catalogue of Mathematical Books," including many of the works of the old mathematicians, has been issued by Messrs. Macmillan and Bowes, Cambridge.

DR. OVERBECK, who owns part of the collections that originally belonged to Alexander von Humboldt, has sent a report about them to the Saxe-Thuringian Naturalists' Society at Halle. He enumerates 290 objects. Dr. Overbeck intends to present Humboldt's collection of minerals to the Mineralogical Museum of Halle University.

THE additions to the Zoological Society's Gardens during the past week include three American Flying Squirrels (*Sciuropterus volucella*) from Florida, presented by Mr. Henry D. Harrison; two Great Eagle Owls (*Bubo maximus*), European, deposited; two Common Wolves (*Canis lupus* ♂ ♀), European, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE NATAL OBSERVATORY.—Mr. Neison, Superintendent of this Observatory, has issued his Report for 1886, and it appears from it that the astronomical work during that year was almost wholly confined to routine observations with the transit instrument, though the meteorological observations were carried on as usual. This partial suspension of activity was due to the fact that only one assistant is now on the staff, and that, through the severe illness of the Superintendent during the first part of the year and his enforced absence in England during the latter part, the assistant, Mr. Grant, was left practically single-handed. The present year will probably show better results, as Mr. Neison returned to his post before the close of 1886, and several needed instrumental improvements and repairs had been successfully carried out. Mr. Neison had commenced an important work connecting the fundamental declinations of the star catalogues of the northern and southern observatories, by means of observations of the differences in zenith distance between 32 selected stars which cross the meridians of the great northern observatories near their zeniths on the one hand, and a set of corresponding southern circumpolar stars on the other.

OLBERS' COMET, 1887.—The following ephemeris for Berlin midnight for this object is in continuation of that given in NATURE of December 1, p. 37:—

PROBABLE NEW CLASS OF VARIABLE STARS.—The Rev. T. E. Espin considers that a number of our variable stars possess characteristics which justify their being formed into a separate class. They are irregular both in period and variation, the latter being usually about 1½ mag., and they show spectra of Secchi's fourth type, *i.e.* like No. 152 Schjellerup. Their changes in brightness are rapid and uncertain. Mr. Espin names 19 Piscium, Birmingham 277, 521, 535, 541, and Espin 116, 154, as belonging to this new class, which perhaps embraces also Birmingham 85, 120, 121, 240, 290, 418, 464, 483, and 502.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 DECEMBER 18-24.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 18

Sun rises, 8h. 4m.; souths, 11h. 56m. 45·5s.; sets, 15h. 50m.: right asc. on meridian, 17h. 43·9m.; decl. 23° 24′ S. Sidereal Time at Sunset, 21h. 38m.

Moon (at First Quarter on December 22, 7h.) rises, 10h. 48m.; souths, 15h. 23m.; sets, 20h. 4m.: right asc. on meridian, 21h. 10·7m.; decl. 16° 43′ S.

Planet.	Rises. h. m.	Souths. h. m.	Sets. h. m.	Right asc. on meridian. h. m.	Declination on meridian. ° ′

GEOGRAPHICAL NOTES.

THE new number of *Petermann's Mitteilungen* contains a letter from Dr. Hans Meyer, written from Taveta, at the foot of Kilimanjaro, giving some details of his ascent of that mountain, and the results of his observations; it is accompanied by a sketch-map. Dr. Meyer, with one white companion and twenty-two natives, started from Mareale's village, at the south foot of the mountain, in the beginning of July, and proceeded to mount the southern slopes. At 1800 metres the last bananas were passed, and at 2000 metres the saturated forest belt was entered, which on the second day was left behind. Immediately above this stretches a broad belt of grass,

and here a north-west line was struck, and for two days the upper edge of the forest was skirted. On the second day Johnston's old camp was reached, where in the water-courses an abundance of large Ericaceous plants was found growing. Here the two beautiful peaks were seen for the first time, and thenceforth only partial glimpses were obtained through the prevailing clouds. Only eight men would go further than this, and when the snow-line was reached five of them refused to go further. On the third day a northerly route was taken over grass-covered lava-fields, with snow-streams sometimes cutting their channels 50 metres deep into the lava. Dr. Meyer made for the saddle which joins the two peaks of Kibo on the west and Kimawenzi on the east. After 6000 paces a level spur of the saddle was reached, where between the great blocks of lava the green meadows marked the upper course of the snow-streams. Here the last traces were seen of *Senecio Johnstoni* in the bed of a brook about 4000 metres high. About 2000 paces further up great cliffs of lava were met with, and here at the snow-line the tent was pitched. Thence, with his companion and three natives, photographic apparatus, and provisions for three days, Dr. Meyer proceeded to ascend to the Kibo crater. After 3000 paces a wild and shattered hill of lava, whence the lava-stream proceeded, was met with; this was the first of a series of such hills, between which the snow lay thick. Turning to the north-west the party made direct for Kibo over the old lava-streams, and at about 5000 metres reached the last cone of ashes before the ascent to the summit itself. Here the two white men encamped (the natives going back), with a night temperature of -11° C. Early next morning they made directly for the east side of the mountain over debris-covered lava, and came on great snow-fields in the spaces between the lava-hills. After a time sleet came on, and, as the sun got higher, clouds covered the mountain, and the temperature fell from $+8^\circ$ C. to -3°. Dr. Meyer's companion became so exhausted he had to drop behind, and he himself suffered greatly. Proceeding onwards, he met with more extensive snow-fields, and higher still with great ice-blocks, and a less steep stretch covered with ice-debris. Some 20 metres beyond this point he saw a great blue wall of ice rise before him to about 34 or 40 metres high, and evidently stretching all round the crater. In Dr. Meyer's exhausted condition, and without ice-axes, to ascend this wall, which evidently surrounded the crater, was impossible. So, after taking some hasty observations and notes, he began his descent, which was accomplished safely. As the wall seems to extend round the east, south, and west sides of the crater, Dr. Meyer concludes that probably the crater itself is filled with ice. It is remarkable that no snow seems to exist at all on the north side. Dr. Meyer promises to give full details on his return home to Leipzig, and these may render his account more intelligible to Alpinists.

OTHER articles in the new number are on "Temperature Abnormalities on the Earth's Surface," by Herr Rudolf Spitaler, accompanied by a map illustrative of the paper; and "Production of Tin in the Riouw-Tongga Archipelago," by Dr. Posewitz.

LIEUT. WISSMANN, whose health is not good, has given a preliminary account of his journey across Africa to the Berlin Geographical Society. He began with a very brief sketch of the first part of his journeyings, which consisted of his first voyage up the Kassai. By his last journey up the Kassai he has determined that its largest tributary is the Kwango. The Sankuru has only half the volume of water possessed by the Kassai above the confluence of the two rivers. From Lulnaburg, Wissmann began his great forward march to the north of the Sankuru and Lomami. A lengthened stay was made on the Lubi, and after crossing the Sankuru the party entered the region of virgin forests. These were found partially peopled by the savage Batetela and the Batua, the latter being the pygmies described in a previous number. Turning south, Wissmann passed through the territory of the marauding Ben Mona, and where on a former journey he found gigantic villages he now found the place depopulated by war and small-pox. From Nyangwe, Wissmann reached the East Coast by Lakes Tanganyika and Nyassa, and the Zambesi. The latter part of the route was through hitherto unexplored territory. Lieut. Wissmann has been compelled to go to Madeira on account of his health, but we believe there is some likelihood of his appearing at the Royal Geographical Society some time next spring.

FROM the full report of recent explorations in Tierra del Fuego, to which we have recently referred in these notes, we have some further information as to the real character of the region. The reports refer chiefly to the main island, which, instead of being a mountainous region of eternal snow, presents great diversity of surface—high mountains, deep valleys, rolling table-lands, fertile plains, numerous lakes, and frequent water-courses. Occupying a large portion of the extreme north, and extending from one extremity to the other of the straits, are continuous chains of mountains, running into peaks several thousand feet high. Adjacent to these mountains on the south is a wide belt of high and rather barren plain, running the entire width of the island. Then succeed lofty table-lands quite covered with forests. South of this is another chain of sierras, and still further south the country opens into an extensive plain, which occupies all the central portion of the island, and is quite desolate of trees except small patches here and there of hardwood and shrubs. The plain is covered in some parts with an abundance of rich grasses. The extreme south is also mountainous, some of the peaks being volcanic, with numerous glaciers and dense forests. The geological formation of Tierra del Fuego exactly corresponds to that of Patagonia. The broken and disjointed mountains, with wide seas running where they have been depressed, are but the continuation of the Andes; while the plains and uplands partake of the same geological characteristics as the Patagonian steppes.

AT Monday's meeting of the Royal Geographical Society the paper read was by Mr. D. D. Daly on his explorations in British North Borneo, in 1883–87. Mr. Daly's paper consisted mainly of an itinerary with minute details of the economic character of the country through which he travelled, and of the people. He gives some interesting information about the numerous bird-nest caves which he met with, and on the methods of collecting the nests. Most of the people are eager head-hunters, but Mr. Daly made treaties with several of the tribes in which they undertook to give over the practice. Mr. Daly went in both from the east and the west side. In the former journey he went up the River Kinabatangan to the centre of North Borneo; in the latter he went a long distance up the Padas River.

ON THE METEORIC IRON WHICH FELL NEAR CABIN CREEK, JOHNSON COUNTY, ARKANSAS, MARCH 27, 1886.[1]

THE Johnson County meteoric iron, the tenth whose fall has been observed, is of more than ordinary interest, because its fall is so well substantiated, because it is the second largest mass ever seen to fall, and, again, because it fell within five months of the date of the ninth recorded fall, that of the Mazapil. It is almost an exact counterpart of the Hraschina (Agram, Croatia) iron, the first of the recorded falls. The Agram iron fell in two fragments, one weighing about 40 kgm., and the other about 9 kgm., the combined weight being about equal to that of the Johnson County iron.

This mass fell about 6 miles east of Cabin Creek, Johnson County, Arkansas, in longitude 93° 17′ W. of Greenwich, latitude 35° 24′ N., within 75 yards of the house of Christopher C. Shandy. Mrs. Shandy states that about 3 o'clock on the afternoon of March 27, 1886, while in her house, she heard a very loud report, which caused the dishes in the closet to rattle, and which she described as louder than any thunder she had ever heard. At first she thought it was caused by a bombshell, and ran out of the house in time to see the limbs fall from the top of a tall pine-tree, which, she says, stands about 75 yards from her dwelling. She did not investigate the matter until her husband came home, about 6 o'clock in the evening, when, in company with John R. Norton, their hired man, they went out to find the cause of the noise that had so startled Mrs. Shandy. They discovered that a large hole had been made in the ground by some falling object. The iron had buried itself in the ground to the depth of 3 feet, and the earth around it to the thickness of 1 inch seemed to be burned. The ground was still warm when the iron was taken out, and the iron itself was as hot as the men could well handle.

The noise was heard 75 miles away, and was likened to a loud report, followed by a hissing sound, as if hot metal had come in contact with water. It caused a general alarm among the people, and teams of horses 25 miles distant, becoming frightened, broke loose and ran away; and in Webb City, Franklin County, on the south side of the Arkansas River, a number of bells kept on sale in a store are said to have been

[1] From the *American Journal of Science*, vol. xxxiii., June 1887.

caused to tinkle. Cabin Creek is on the north side of the Arkansas River.

Mr. B. Caraway says it was heard by fully 1000 people, and that he heard two loud reports at Alma, Crawford County, 75 miles away, at 3 o'clock on March 27, 1886. The report was also heard at Russellville, and in the adjoining county of Pope.

Prof. H. A. Newton, who has kindly interested himself in this matter, says that the data furnished indicate that the mass must have fallen nearly from the zenith. This was the direction

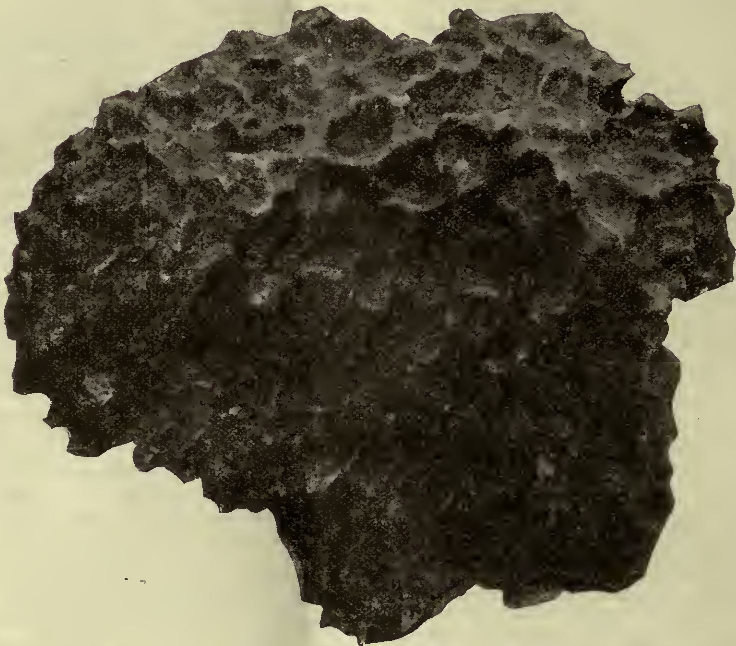

FIG. 1.—Upper Side.

FIG. 2.—Lower Side.

Johnson County, Arkansas. (Scale two-ninths.)

of the end of its path, the earlier portion being more inclined to the vertical, as the path must be affected by gravity and the resistance of the air. The earlier direction must have been from the north-east, and more nearly from the east than the north.

The mass is in general quite flat and very irregular, resembling strongly a mass of molten metal thrown on the ground and then pitted. The illustration of the Agram[2] mass figured

[2] "Beiträge zur Geschichte und Kenntniss Meteorischer Stein- und Metall-massen," by Dr. Carl von Schreibers. Wien, 1820, folio, plate viii.

by Von Schreibers could be mistaken for the upper side of this, were it not that this is larger. It measures 17½ inches (44 cm.) by 15½ inches (39 cm.), while the Agram measures 15½ by 12 inches. A high ridge, 5 inches high at the highest point (12·5 cm.), runs through the centre. One half of the mass is not over 3 inches (7·5 cm.) thick, part of it is only 2 inches (5 cm.), and around the edge it is only 1 inch, or less. It is only exceeded in size, among the irons seen to fall, by the Nejed, Central Arabia, now in the British Museum, which fell in the spring of 1865, and weighs 59·420 kgm. The weight is 107½ lbs. (48·750 kgm.), and it is intact with the exception of three small points, weighing not more than 2 ounces in all, which were broken off. One of these is seen in the etched figure, another was sent to Prof. Clarke by Colonel Betten to be analyzed, and the third piece was lost.

The two sides are wholly dissimilar (see Figs. 1 and 2[1]). In fact, one would scarcely suppose that they belonged to the same mass. The upper side is ridged and deeply dented, while the lower side is flat and covered with shallow but very large pittings. On top the colour is in many places almost tin white without any coating whatever, and the pittings are very deep, and usually quite long, like finger depressions made in potters' clay. These depressions measure from 2 cm. to 4 cm., and from 1 cm. to 4 cm. This side is remarkable for striæ showing the flow and burning, and all running from the centre toward the edge, identical with those in the Rowton, Nedagolla, and Mazapil irons, but on a larger scale. Some of them are thinner than a hair, and yet twice as high (like a high knife-edge), and they are from 1 to 4 inches long. In one space of 5 cm. twenty are arranged side by side, and on one small part which is black, there are fifty lines in 1 inch of space (25 mm.), all running in the same direction. Near all the pointed edges the fused metal has flowed and cooled, so as to hang like falling water. The striæ and marks of flowing are around the edges of the upper surface (Fig. 1). On the under side pittings are very shallow,

FIG. 3.

but much broader, one depression, apparently made up of four pittings, being 20 cm. long, and 9·5 cm. wide. The whole side is coated with a black crust, 1 mm. thick, and having minute round bead-like markings. On one of the indentations of the lower edge the crust has a strikingly fused appearance, as if a flame had been blown on it from the other side. In reality this edge is undoubtedly the place where a greater amount of burning took place when the body was passing through the air. Seven small, bead-like lumps, from 5 mm. to 10 mm. in size, which are visible on this side, are drops of metal that were entirely melted, and flowed and cooled so that they resemble drops of a thick liquid. There are also to be seen what appear to be cracks, fifteen in number, and nearly as thin as a hair. One of these is 10 cm. long, and extends from the highly-fused edge above mentioned towards the centre. The others are from 3 cm. to 5 cm. long. These are so evenly arranged that they are without doubt *Reichenbach lamellen*, in which the inner troilite has been burnt out. If such is the case, they are as abundant as in the Staunton (Va.) meteoric iron.

On the upper side ten nodules of troilite are exposed, measuring from 33 mm. in diameter, to 55 mm. long, and 25 mm. wide. On the lower side there are twelve such nodules exposed, 13 mm. in diameter, while the largest measures 19 mm. by 39 mm. On the upper side these nodules are coated in spots with a black crust, similar to that found on the mass, but on the lower side the crust extends completely around the side of the nodules, showing the fusion very plainly. The troilite is very bright and fresh, like a newly broken mineral, and on the upper side one of the nodules shows deep striation, suggesting that the entire nodule is one crystal, and the exposed part is only one side of it. In some cases where the nodules were broken, they were found to be iridescent. This is one of the octahedral irons showing the Widmanstätten figures beautifully on etching (see Fig. 3), and is one of the Caillite groups of Stanislas Meunier and of the *mittlere lamellen* of Brezina. The lamellæ are 1 mm. wide, and the markings more closely approach the Rowton[1] and Mazapil[2] irons. Fig. 4 shows the etching on the surface of the unpolished exterior, there being no crust. The lower end of the figure, which is flat, was produced by the hammering off of the piece; but the etching was really finer where it was done on the natural surface of the iron. The specific gravity of the small piece figured is 7·773. Troilite, as before stated, is very abundant in the mass. Schreibersite and carbon have also been found

FIG. 4.

between the laminæ. Chlorine is present only in slight quantity, as scarcely any deliquescence has been observed.

The following is a comparative table of analyses of meteoric irons most nearly approaching this in composition :—

THE ROYAL HORTICULTURAL SOCIETY.

THE Council of the Royal Horticultural Society request the horticulturists of the United Kingdom to read and consider the following statement and appeal :—

1. The grounds at South Kensington, known as the Gardens of the Royal Horticultural Society, having been devoted to the Imperial Institute, the Council endeavoured, in obedience to the wishes so graciously expressed by Her Majesty the Queen, the Patron of the Society, to obtain from the Royal Commissioners of the 1851 Exhibition such a site as would justify them in advising the Fellows to remain at South Kensington.

2. The Royal Commissioners were, however, unable to offer any adequate site, and gave the Council distinctly to understand that the erection of offices, committee-rooms, &c., on their land would not be held to confer any claim whatever, either legal or moral, to the use of the Conservatory and Gardens for the purposes of the Society. The negotiations consequently came to an end. An informal offer has since been made by the Royal Commissioners to let a portion of the Gardens and the Conservatory to the Society at a guaranteed rent of £1000 a year, which with rates, taxes, and maintenance would involve an expenditure of £2000 a year at least, a sum far beyond the resources of the Society.

3. The Society has been in existence for eighty-three years, having been founded in 1804, and incorporated by Royal Charter in 1809. It has done much to advance the interests of practical and scientific horticulture, and it is the recognized authority on all horticultural questions. In addition to the valuable work of the Scientific Committee, presided over by Sir J. D. Hooker, K.C.S.I., C.B., F.R.S., new and rare plants, fruits, and vegetables, collected abroad or raised at home, have been continually submitted, in large and increasing numbers, to the judgment of the Fruit and Floral Committees, whose verdicts are accepted without question. The Society has also continuously carried on valuable trials of plants, fruits, and vegetables, at Chiswick. It has published during the last three years the following, viz. :— "Report of the National Apple Congress held at Chiswick, October 1883," "Report of the Orchid Conference held at South Kensington, May 1885," "Report of the National Pear

Conference held at Chiswick, October 1885," "Report of the Primula Conference held at South Kensington, April 1886, and of the Orchid Conference held at Liverpool, June 30, 1886," "Report on the Effects of Frost on Vegetation during the Severe Winters 1879-80, 1880-81, published in 1887."

4. The Council are of opinion that the connection of the Society with South Kensington, however promising at first, has proved adverse to its true interests and permanent welfare. They recognize that altered circumstances require a complete re-organization of the Society on a more popular basis. They believe that, while local Horticultural Societies attract local support, a central Metropolitan Society (to which local Societies may be affiliated) is, in the interests of horticulture, indispensable. Under analogous circumstances the Royal Agricultural Society prospers, although there are local Societies in every county of the Kingdom.

5. The Council do not believe that the Society can be carried on any longer under the trammels of the existing Charter, which was granted in 1860 in view of a wholly different state of things; nor do they think a Charter will be requisite for its future working. They believe that the numbers of the Council should be considerably increased and their mode of election modified and made popular, and that the ordinary work of the Society should be carried on by Committees, under powers delegated to them by the Council. They hold that the Society should henceforth devote itself strictly to the advancement of practical and scientific horticulture.

6. The view of the Council is that the expenditure of the Society should be reduced as much as possible, and its resources devoted to the following objects:—

(1) The maintenance of the Chiswick Gardens and the conduct of plant, fruit, and vegetable trials there; and possibly the establishment of a School of Gardening.

(2) The immediate engagement of such premises in a convenient and central situation as may suffice for office requirements, the safe housing of the Lindley Library, the meetings of the Society's Committees, and its fortnightly shows, to the maintenance of which they attach great importance.

(3) The publication of periodical Reports of the work done at Chiswick, and by the Society's Committees, and on horticultural subjects generally.

7. For many years the nature of the accommodation which the Society has been able to obtain at South Kensington has virtually prevented meetings being held for the discussion by the Fellows of points of interest in the practice of horticulture. It is essential that these meetings should be resumed, and it is believed that they will be of great value in bringing together those who take an active part in British horticulture. It is also hoped that such meetings would give an opportunity for the consideration of the numerous directions in which the rural economy of the country seems likely to be modified by the substitution of horticultural for agricultural methods.

8. The Council would recommend that the subscription should be in future £2 2*s.* for Fellows, and that a grade of Member or Associate, at £1 1*s.*, should be created for professional and practical gardeners, who have rarely hitherto belonged to the Society. They calculate that the maintenance of Chiswick will cost £1500 a year, and that for the other purposes of the Society a further sum of not less than £1500 a year will be required. During 1887, 150 Fellows have paid £4 4*s.*, and 623 Fellows £2 2*s.*, making a total of £1938 6*s.*, a sum altogether insufficient for the working and requirements of the Society.

9. In conclusion, the Council believe that the extinction of the Royal Horticultural Society would be regarded by all interested in horticulture as a national loss. The history of the Society, and the good work it has done and is doing, entitle it to the consideration and support of the horticultural world, to whom the Council make this appeal. They address it with equal confidence to amateurs and to the trade, in the belief that their interests are identical, and that for the protection and advancement of these interests the maintenance of the Royal Horticultural Society is essential. The Council have had difficult duties to perform. While they are willing to continue to discharge these duties, if desired, they believe that the best course would be for them to place their resignations in the hands of the Fellows, at the end of the year, so as to leave the Society entirely unfettered. But they consider it due both to the Fellows and to themselves to say that, unless they receive assurances of adequate support, in response to this appeal, the Society must necessarily come to an end.

10. The favour of an early answer is requested on the inclosed form. The Donations would be devoted to the cost of establishing the Society in its new home and to similar purposes.

On behalf of the Council,

TREVOR LAWRENCE, *President.*

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Thurston Prize at Caius College, value £54, for the best original investigation by a member of the College in the past three years in physiology, pathology, or practical medicine, has been adjudged to Mr. C. S. Sherrington, M.A., M.B., Fellow of the College.

The Sedgwick Memorial Committee having declined to assent to the building of rooms for teaching purposes with the Sedgwick Fund, while waiting the building of a complete museum; and other proposals having been made, a syndicate has been appointed to plan out the entire disposal of the sites surrounding the new museums, so as to satisfy as many scientific requirements as possible.

Mr. E. C. Dowson has been appointed Demonstrator of Mechanism and Applied Mechanics in succession to Mr. Ames.

Next term the General Board of Studies will nominate a University Lecturer in Pure Mathematics, in consequence of the resignation of Mr. Macaulay. The stipend is £50 per annum, and the appointment will be for five years. A preference will be given to a lecturer who would take subjects not at present represented. Among these are theory of equations, theory of numbers, and projective geometry.

Scholarships in Natural Science will be competed for this month or next at Gonville and Caius, King's, Jesus, Christ's, St. John's, Trinity, Emmanuel, and Sidney Sussex Colleges. The tutors will give full information.

A Clothworkers' Exhibition for Natural Science, tenable at Oxford or Cambridge for three years, will be awarded next July by an examination under the Oxford and Cambridge Schools Examination Board. Particulars may be obtained from the Censor of Non-Collegiate Students, Cambridge.

Another general modification of examinerships in natural science is proposed, which we shall refer to when it has been discussed by the Senate.

SCIENTIFIC SERIALS.

American Journal of Science, November.—On the relative motion of the earth and luminiferous ether, by Albert A. Michelson and Edward W. Morley. A complete and satisfactory explanation of the aberration of light is given by Fresnel's undulatory theory, which assumes, first, that the ether is supposed to be at rest except in the interior of transparent media; secondly, that in this case it moves with a velocity less than that of the medium in the ratio $\frac{n^2 - 1}{n^2}$, where n is the index of refraction. The second hypothesis having been fully established by Fizeau's celebrated experiment, the first alone is dealt with in this paper. From the delicate researches here described, which have been carried out by the aid of the Bache Fund, it is inferred that, if there be any relative motion between the earth and the luminiferous ether, it must be small, quite small enough entirely to refute Fresnel's explanation of aberration. It is further shown that the theories of Stokes and Fresnel also fail, and that it would be hopeless to attempt to solve the question of the motion of the solar system by observations of optical phenomena at the surface of the earth.—On the existence of carbon in the sun: contributions from the physical laboratory of Harvard University, by John Trowbridge and C. C. Hutchins. Without discussing the well-known observations of Abney on the absorption-bands in the solar spectrum at high altitudes, or Siemens's hypothesis of the presence of carbon vapour in interplanetary space, the authors here study the remarkable character of the carbon spectrum formed by the voltaic arc in air between carbon terminals, drawing attention to the evidence presented by the juxtaposed solar spectrum of the existence of carbon in the sun. They conclude that at the point of the sun's atmosphere where the carbon is volatilized, the temperature of the sun approximates to that of the voltaic

arc.—History of the changes in the Mount Loa craters, by James D. Dana. A recent visit of ten weeks to Hawaii has enabled the author to carry out the purpose expressed in his communication of last August. Here are presented only such facts as bear on the history of Kilauea since 1832, the general summary and conclusions being reserved for future numbers of the journal. The subject is illustrated with plates of Kilauea Crater, its lava floor, and the Halema'uma'u basin.—Is there a Huronian Group? (continued), by R. D. Irving: For the extensive region stretching from the north side of Lake Huron to the Mississippi it is here concluded that the succession of rocks in ascending order is from the great complex of crystalline schists, gneiss, and granite through the Huronian Group, mainly of detrital rocks, to the Keweenaw, of interleaved detrital and eruptive beds and the Potsdam, or Upper Cambrian Sandstone, with great structural breaks between the first and second, and second and third groups. The Huronian series itself, traceable throughout the Lake Superior province, is shown to be of clastic and sedimentary nature, of great volume, and structurally and chronologically separated from all other rock formations. The term *Agnotozoic*, originally suggested by Chamberlain, is proposed to cover the whole geological interval lying between the base of the Cambrian and the summit of the Archæan crystallines.—Description of an iron meteorite from St. Croix, County Wisconsin, by Davenport Fisher. This specimen, discovered in 1884 on a farm in Hammond Township, weighed 53 pounds, and yielded, on analysis: iron 89·78, nickel 7·655, cobalt 1·325, phosphorus ·512, silica ·562, with traces of carbon, copper, and tin.—The Rockwood meteorite, by J. Edward Whitfield. Picked up in March 1887 in a field in Cumberland County, Tennessee, this meteorite yielded, on analysis: iron 87·59, nickel 12·09, with traces of cobalt and copper.—Principal characters of American Jurassic Dinosaurs, by O. C. Marsh. This paper, forming Part 9 of the whole series, deals with the skull and dermal armour of Stego aurus, a nearly complete skeleton of which has lately been discovered. The specimen here described constitutes a new and very distinct species, for which the name of *S. duplex* is proposed.

THE *Journal of Botany* for September commences with an important paper, by Mr. Geo. Massee, on the growth and origin of multicellular plants. He describes the structure and mode of formation of the gelatinous membrane exterior to the true cellulose-wall, and extending continuously over the whole plant, which is not uncommon in Algæ, and nearly universal in the Florideæ. It can be easily shown that the formation of the cellulose-wall never precedes that of this mucilaginous sheath, and its function is rather a supporting than a protecting one. The mucilaginous sheath is composed of protoplasm, or of a substance very nearly allied to protoplasm. It is usually homogeneous, even after the appearance of the cell-wall; but in *Pandorina* the innermost portion consists of parallel rods placed end to end on the cell-wall. The portion composed of rods stains readily with methyl-violet and other aniline dyes, while the homogeneous portion does not. The remainder of the space in this number, and in those for October and November, is chiefly occupied by monographs or descriptive papers on new exotic species, or to others mainly of interest to English botanists. It is a remarkable evidence that the old-fashioned species-botany is not altogether dead in this country, that no fewer than three species of flowering-plants have been added to the flora of these islands during the past year—all in Scotland.

WE have received the numbers of the *Botanical Gazette*, published at Crawfordsville, Indiana, for August-November 1887. They furnish satisfactory evidence of the activity of botanical science in the Western States of North America. The articles and shorter paragraphs, where they are original, chiefly concern the flora of the district; but we may mention as of more general interest:—Vegetable parasites and evolution, by W. G. Farlow; development of the Umbellifer fruit, by J. M. Coulter and J. N. Rose; and plant odours, by A. J. Stace. The first of these papers is the Presidential Address given by Prof. Farlow before Section F of the American Association for the Advancement of Science. In it he treats specially of the phenomenon of "symbiosis" in lichens, and of "mycorrhiza." As to the former he doubts whether there is any sufficient evidence of the usual statement that the lichen-gonidia derive benefit from their association with the fungus.

THE *Nuovo Giornale Botanico Italiano* for October contains two papers only—on the Muscineæ of the Island Giglio, off the coast of Tuscany, by Signor A. Bottini; and an enumeration of plants gathered in the Balearic Islands in 1885, by Signor P. Porta. To the latter is prefixed an account of the physical geography and natural productions of the islands, and a *résumé* of previous botanical explorations.

Revue d'Anthropologie, troisième série, tome ii., sixième fasc., 1887 (Paris).—On the stature of the ancient inhabitants of the Canary Islands, by Dr. R. Verneau. The writer draws attention to the discrepancies to be found in the narratives of older chroniclers and travellers as to the stature of the islanders at the time of the discovery of the Canarian Archipelago. Thus while the Portuguese explorers sent out by Alphonso IV. of Portugal in 1341 described the natives as of the same medium height as the Portuguese, some of the Spaniards who took part in the conquest of the islands 200 years later maintained that they had seen the skeleton of a man 24 feet long, and spoke of living men who were respectively 9 and 14 feet in height. Setting aside the obvious absurdity of such estimates, Dr. Verneau is of opinion that in regard to some of the islands, as Lancerotte and Fortavente, it may be fairly assumed that the Guancho natives of pre-Spanish times were a tall, well-developed race, since such is still the character of the people in isolated villages in those islands which have been the least exposed to contact with strangers and invaders, while he found that the bones recovered from ancient local burying-grounds of the latter island indicated a mean height of 1·84 metre for men, and 1·60 for women. Amalgamation with invading races of lower stature seems to have lowered the mean height of the people, more especially in the south-east of the archipelago. Dr. Verneau finds that in regard to cephalic characteristics, the ancient Guanchos closely resembled the Cro-Magnon type, and he believes he has found incontrovertible proof that Numidian, Semitic, and other North-African races were among the earliest invaders of the Canaries.—On criminal anthropology, by M. Topinard. This is virtually a review of the Italian writer C. Lombroso's work on "Criminal Man," to whose theory of the physical and atavic character of criminality he is strongly opposed. Signor Lombroso believes that the criminal is born with irrepressible tendencies to crime, and that certain physical anomalies characterize the born malefactor. M. Topinard disputes not merely his mode of reasoning, but the facts which he adduces in support of his theories, and the accuracy, or applicability, of his numerous statistical tables. In conclusion, he not only shows the unscientific methods of inquiry followed by Lombroso, but he attacks the use of the denomination of "criminal anthropology," since the term implies the possibility of grouping together as fixed characteristics a number of phenomena which depend upon endless complications of psychical and social causes whose varied action on physical conditions does not admit of strict scientific determination.—Contributions to the sociology of the Australians, by M. Elisée Reclus. In this continuation of a series of papers which appeared in this journal last year, M. Reclus treats of spirits and sorcerers. The author uses his materials dexterously, and has compiled a highly interesting memoir on the superstitions and mythological fancies of these races, but as the greater part of the narrative has been derived from English sources it has little novelty or interest for English readers, who will find few facts in it with which they are not already familiar through the writings of Taplin, Woods, Grey, &c. —On lacustrine and lake-villages and pile-dwellings, by M. Pompeo Castelfranco. After a general consideration of the subject, more especially in regard to Italy, and the references bearing on it in the writings of Italians from the middle of the sixteenth century to the present times, the author gives the history of the discovery of lacustrine dwellings in Northern Italy which was made in 1862. Since that period almost all the lakes of that region have supplied rich yields of flints and pottery and bronzes, although none more so than Lake La Garda. The most interesting of these pile stations is that of La Lagozza, whose area of 2400 square metres was not wholly revealed till 1880. On examining the various piles which he had caused to be extracted from the superincumbent peat, Signor Castelfranco recognized that some were of birch (*Betula alba*) and others of fir and pine (*Pinus picea*, *P. silvestris*). Various flint and polished stone implements were found, but with the exception of a bronze fibula, which probably belongs to a later age than the original pile-dwellings, not a vestige of metal has been discovered at Lagozza. Potsherds and shreds of linen fabric have been found, but the most remarkable thing is the complete absence of bones, or any other animal remains; and while the

abundance of seeds, grains, nuts, acorns, &c., plainly indicates the vegetable character of the diet of these lake-dwellers, the appearance of masses of husked wheat and barley proves that they practised agriculture, and understood how to thrash and winnow the grain. Considerable interest attaches to the discovery below the peat, in what is characterized as the archaic bed, of large masses of seeds, determined by Prof. Sordelli as identical with those of the cultivated so-called Indian poppy (*Papaver somniferum*). Heer has recorded in the Swiss pile-dwellings the presence of poppy seeds which he referred to *P. seligerum*, but whether the Italian and the Swiss remains belong to the same or different species of poppy, the use to which they were put by primæval men in the two countries remains an unsolved problem.—On the Polynesians, their origin, migrations, &c., by MM. Lesson and Martinet. The purpose of this work is to refute the three most generally accepted theories regarding the origin of these races, viz. whether they are survivals from an almost wholly submerged continent, or whether they are of American, or of Asiatic descent; and to maintain the novel hypothesis that they are descendants of Maoris of the Middle Island of New Zealand. These views the authors endeavour to support by showing close analogies of language between the two peoples, affinities between certain names of places and of deities used by both, and frequent identity in forms of belief, rites, and superstitions. They further point out that the natives of the Marquesas, who are regarded as of the purest Polynesian race, use the same word, Havaiki, as the Maoris to denote their original ancestral home. From these and numerous other linguistic affinities the writers conclude that the Maoris are the autochthonic ancestors of the Polynesians, and that the Maori language is the mother speech of all the Polynesian dialects.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 24.—"On the Motion of a Sphere in a Viscous Liquid." By A. B. Basset, M.A. Communicated by Lord Rayleigh, D.C.L., Sec.R.S.

The determination of the small oscillations and steady motion of a sphere which is immersed in a viscous liquid, and which is moving in a straight line, was first effected by Prof. Stokes in his well-known memoir "On the Effect of the Internal Friction of Fluids on the Motion of Pendulums" (Camb. Phil. Soc. Trans., vol. ix. part 2, p. 8); and in the appendix he also determines the steady motion of a sphere which is rotating about a fixed diameter. The same subject has also been subsequently considered by Helmholtz and other German writers; but, so far as I have been able to discover, very little appears to have been effected with respect to the solution of problems in which a solid body is set in motion in a viscous liquid in any given manner, and then left to itself.

In the present paper I have endeavoured to determine the motion of a sphere which is projected vertically upwards or downwards with given velocity, and allowed to ascend or descend under the action of gravity (or any constant force), and which is surrounded by a viscous liquid of unlimited extent, which is initially at rest excepting so far as it is disturbed by the initial motion of the sphere.

In solving this problem, mathematical difficulties have compelled me to neglect the squares and products of velocities, and quantities depending thereon, which involves the assumption that the velocity of the sphere is always small throughout the motion; and I have also assumed that no slipping takes place at the surface of the sphere. The problem is thus reduced to obtaining a suitable solution of the differential equation—

$$D\left(D - \frac{1}{\mu}\frac{d}{dt}\right)\psi,$$

where

$$D = \frac{d^2}{dr^2} + \frac{\sin\theta}{r}\frac{d}{d\theta}\left(\operatorname{cosec}\theta\frac{d}{d\theta}\right).$$

ψ is Stokes's current function, and μ is the kinematic coefficient of viscosity. The required solution is obtained in the form of a definite integral by a method similar to that employed by Fourier in solving analogous problems in the conduction of heat; the resistance experienced by the sphere is then calculated, and the equation of motion written down and integrated by successive approximation on the supposition that μ is a small quantity. The values of the acceleration and velocity of the sphere to a third approximation are found to be

$$v = f\epsilon^{-\lambda t} .. V\lambda\epsilon^{-\lambda t} -$$

$$fka\sqrt{\frac{\mu}{\pi}}\{(\tfrac{1}{2} - \lambda t)\phi(t) + \sqrt{t}\} + fk^2a^2\mu t\epsilon^{-\lambda t}(1 - \tfrac{1}{2}\lambda t),$$

$$\dot{v} = \frac{f}{\lambda}(1 - \epsilon^{-\lambda t}) + V\epsilon^{-\lambda t} -$$

$$fka\sqrt{\frac{\mu}{\pi}}\left\{\left(t + \frac{1}{2\lambda}\right)\phi'(t) - \frac{\sqrt{t}}{\lambda}\right\} + \tfrac{1}{2}fk^2a^2\mu t^2\epsilon^{-\lambda t},$$

where

$$f = \frac{(\sigma - \rho)g}{\sigma + \frac{1}{2}\rho}, \quad k = \frac{9\rho}{a^2(2\sigma + \rho)}, \quad \lambda = k\mu,$$

$$\phi(t) = \int_0^t \epsilon^{-\lambda\tau}(t - \tau)^{-\frac{1}{2}}\,d\tau,$$

ρ being the density of the liquid, σ that of the sphere, and a its radius.

It thus appears that, after a very long time has elapsed, the acceleration will vanish and the motion will become steady. The terminal velocity of the sphere is $f\lambda^{-1}$, which is seen to agree with Prof. Stokes's result.

If the sphere were projected with velocity V, and compelled by means of frictionless constraint to move in a horizontal straight line, the values of the acceleration and velocity would be obtained from the preceding formulæ by expunging the terms $f\epsilon^{-\lambda t}$, $f\lambda^{-1}(1 - \epsilon^{-\lambda t})$, in the expressions for $\dot{v}$ and v respectively, and then changing f into $-V\lambda$.

The preceding results can only be regarded as a somewhat rough representation of the actual motion, for (1) the square of the velocity has been neglected; (2) no account has been taken of the possibility of hollow spaces being formed in the liquid; (3) if the velocity of the sphere became large, the amount of heat developed would be sufficient to vaporize the liquid in the immediate neighbourhood of the sphere, and the circumstances of the problem would be materially changed.

In the latter part of the paper I have considered the problem of a sphere, surrounded by a viscous liquid, which is set in rotation with given angular velocity, Ω, about a fixed diameter, and similar results are obtained. To a first approximation the angular velocity is equal to $\Omega\epsilon^{-\lambda t}$, where λ is a positive constant, which shows that the motion ultimately dies away.

December 8.—"The Sexual Reproduction of *Millepora plicata*." By Dr. Sydney J. Hickson.

Considerable attention has of recent years been paid by naturalists to the phenomena connected with the sexual reproduction of the Hydromedusæ. Stimulated by the brilliant results obtained by Allman and Weismann, several naturalists have investigated the structure of the various Medusæ and medusoid gonophores found in the group, the origin of the sexual cells, and the development of the embryo. These results have, on the whole, been so interesting and important that it was confidently anticipated that an investigation of the phenomena connected with the sexual reproduction of Milleporidæ would yield results of considerable interest. The systematic position of this family has always been a doubtful one, and naturalists were agreed that until the sexual reproduction was described, the position assigned to them could only be considered a temporary one.

It was my good fortune when in Talisse Island, North Celebes, to find on the reef just opposite my hut a fine specimen of *Millepora plicata* in vigorous growth. I visited it whenever the tide allowed, in the hopes of seeing the polyps fully expanded, and of being able to search them for any form of gonophore they might possess. In this, however, I was disappointed. Notwithstanding all my precautions, I never succeeded in finding the polyps more than partially expanded, and I could find no gonophores.

Having collected some specimens and dissolved the calcareous skeleton in strong acid, I discovered in the canals of the cœnosarc both the ova and the spermospores; but the unforeseen difficulties to be met with in working in a hot little bamboo hut in a tropical island prevented me from making any satisfactory series of sections, and I was reluctantly obliged to leave the further investigation of the subject until I returned to a laboratory in Europe.

Since my return home I have made a large number of prepa-

rations, and the results I have obtained may be summed up as follows :—

Both the male and female sexual cells arise in the ectoderm of the cœnosarcal canal system. At an early stage they perforate the mesoglœa and take up a position in the endoderm.

The ova at an early stage become stalked. The stalk of the ovum, which is simply a modified pseudopodium, serves to keep the ovum attached to the mesoglœa. The stalk is sometimes completely withdrawn, and the ovum by amœboid movements migrates along the lumen of the canals to a more favourable locality.

Maturation and impregnation occur while the ovum is still in the canals.

The mature ovum is very small (1/100 mm. in diameter), and is alecithal; nevertheless, it does not segment.

The germinal vesicle of the fertilized ovum splits up into a number of fragments, which, after a curious series of movements in the ovum, are eventually scattered over its substance.

By the time these fragments are thus scattered over the ovum, they have reached a considerable size, and, from faint markings in the substance of the ovum, no doubt can be retained that they are in reality the true nuclei of a morula stage in the development of the embryo. The embryo next assumes the form of a solid blastosphere, and its subsequent history is lost.

It will be a very interesting point to determine the precise mode of discharge of the embryo. I am very strongly of opinion that the embryo is discharged by the mouth of the gastrozooid, but I was, of course, unable to observe this in the living state. Whether this is correct or not, the fact remains that I have been unable to find in any of my preparations any trace of a free or fixed gonophore, containing either embryos or ova.

In the development of the spermatoza, a similar phenomenon is found to that in the development of the embryo. The spermospore does not divide into a sperm-morula, the nucleus alone fragments, and the subsequent formation of spermoblasts does not occur until a very late stage. When the spermoblasts are mature they are found in simple *sporosacs* on the dactylozooids. The sporosacs exhibit no traces of any medusoid structure.

These researches tend to prove that the Milleporidæ belong to a separate stock of the Hydrozoa from the Hydromedusæ, a stock which probably never possessed free-swimming medusiform gonophores.

There seems to be no true relationship between Millepora and Hydractinia. The absence of segmentation in the developing embryo may probably be accounted for by the amœboid movement which it exhibits after development has commenced. The evidence before us does not support the view that the ovum of Millepora formerly contained much yolk, and has subsequently lost it.

Physical Society, November 26.—Dr. Balfour Stewart, President, in the chair.—Mr. Asutosh Makhopadhyay was elected a member of the Society.—The following communications were read :—On the analogies of influence-machines and dynamos, by Prof. S. P. Thompson. The author pointed out that in nearly all influence-machines there are two stationary parts ("inductors") electrified oppositely, which are analogous to the field-magnet of dynamos, and a revolving part carrying "*sectors*" which correspond to the "*sections*" of an armature. To prevent ambiguity Prof. Thompson proposes to call the inductors "*field plates*," and the revolving parts as a whole an "*armature*." In the Wimshurst machine both field plates and armature rotate, and each acts as field plates and armature alternately. In the two field plate influence-machines there are four and sometimes six brushes. Two of these act as potential equalizers, two as field plate exciters, and the remaining two (if any) are generally placed in the "discharge" or external circuit. The Holtz machine having only four brushes, two serve the double purpose of potential equalizers and discharge circuit, and this machine excites itself best when the discharging rods are in contact. In this respect it resembles a series dynamo which only excites itself when the external circuit is closed, but on opening the circuit (say by inserting an arc lamp) produces remarkable effects. So in the Holtz machine on separating the discharging knobs a shower of sparks results. The Toepler machine (made by Voss) having six brushes resembles a shunt dynamo, and excites itself best on open external circuit. Analogies were traced between Thomson's replenisher and the Griscom motor. Armatures of influence-machines, as in dynamos, can be divided into ring, drum, disk, and pole armatures, and examples of each kind were mentioned. The "Clark Gas Lighter" is a good example of a drum armature, and a diagram showing the internal arrangements was exhibited. An example of an analogue to the compound dynamo was mentioned as existing at Cambridge, in the form of a Holtz machine believed to have been modified by Clerk Maxwell. Another analogue with dynamos is found in the displacement of the electric field when the armature is rotated, just as the magnetic field of a dynamo is shifted round in the direction of rotation. Further analogies were traced between "critical velocity" of dynamos (which depends on the resistances in the circuit) below which they do not excite themselves, and a similar critical velocity of influence-machines; *e.g.* in a Wimshurst or Voss machine, the potential equalizing circuit should have a low resistance if they are to excite themselves readily. Self-exciting dynamos excite better when the iron is bad and retains the magnetism, and influence-machines excite better when the field plates are made of paper or such substance as can well retain a residual charge. Finally an apparatus analogous to Thomson's "water-dropping accumulator" was exhibited, in which an electric current was generated by mercury falling down a tube between the poles of a magnet.—On the effect produced on the thermo-electric properties of iron when under stress or strain by raising the temperature to a bright red heat, by Mr. Herbert Tomlinson. In June last the author described some remarkable "effects of change of temperature on twisting and untwisting wires which have suffered permanent torsion," of which the present paper is a continuation. It is found that at or about the critical temperature (a bright red heat) mentioned in the previous paper, a sudden E.M.F. is generated at the junction of two iron wires, one of which is under stress or has suffered permanent strain, and the other in an unstrained state. By suddenly bringing a red-hot iron wire in contact with cold iron, an E.M.F. of about 1/20 volt is produced. If copper be used the E.M.F. is about $\frac{1}{3}$ volt. The author also showed that if one part of an annealed iron wire is heated to a bright red by a bunsen flame, an E.M.F. is generated if the position of the flame is slightly altered, the direction of the E.M.F. depending on the direction of the displacement. Prof. Ayrton believed the high E.M.F. exhibited by hot and cold copper was really due to oxide of copper; and Prof. S. P. Thompson said that different effects could be produced by using the oxidizing or reducing parts of the flame in heating the wire.—On the method of discriminating real from accidental coincidences between the lines of different spectra, with some applications, by Mr. E. T. J. Love.

December 10.—Prof. W. E. Ayrton, Vice-President, in the chair.—Mr. E. A. C. Wilson, and Mr. W. E. Sumpner were elected members of the Society.—Mr. H. G. Madan described the optical properties of phenyl-thio-carbimide. This body, derived from aniline, is a colourless liquid, density 1·35° C., and of high boiling-point 222° C. The refractive indices for the A and G lines are 1·639 and 1·707 respectively. It is thus seen to be a highly refractive liquid, and to have about the same dispersive power as carbon-bisulphide, whilst its use in prisms is unattended by many of the risks and inconveniences experienced with carbon-bisulphide. The dispersion at the blue end of the spectrum is very marked. Being less mobile than carbon-bisulphide, it is less affected by convection currents. The "refractive equivalent" calculated from its chemical constitution differs considerably from the observed value, and this difference the author believes due to the presence of the phenyl radicle and sulphur atom. A polarizing prism made on Jamin's plan, but using phenyl-thio-carbimide as the liquid, gives a fairly wide angular field (about 25°). Mr. Hilger stated that there was no great need of liquid prisms now, for very dense flint glass could be obtained with mean index of about 1·8. Dr. Perkin has recently supplied him with Canada balsam perfectly colourless, and which does not tarnish the polished faces of spar; hence one of the greatest objections to the use of Canada balsam in spar polarizing prisms has been removed. Dr. Gladstone pointed out that the constants for the phenyl radicle and for sulphur atoms had been determined, and thought the calculated "refractive equivalent" obtained by including these would be much nearer the observed value than the one given by Mr. Madan.—On the recalescence of iron, by Mr. H. Tomlinson. If an iron bar which has suffered permanent strain be heated to a white heat and allowed to cool, the brightness at first diminishes and then reglows (recalesces) for a short interval. Under favourable circumstances as many

as seven reglows have been observed during one cooling. Generally two decided ones are observed, one between 500° and 1000° C., and the other below 500° C. The effects the author believes due to "retentiveness" of the material, somewhat similar to the causes of residual magnetism and residual charge of a Leyden jar. A table of experimental results, giving the torsional elasticity and internal friction at different temperatures, for iron wire, showed sudden increases in internal friction at temperatures of about 550° and 1000° C. The table also shows that the torsional elasticity slowly decreases as the temperature increases, whereas the internal friction increases enormously. This explains why bells cease to emit musical notes when heated. The author finds that the recalescence at the higher temperature is not appreciably accelerated by mechanical vibration such as hammering, &c., but those occurring at lower temperatures are greatly influenced by such treatment and by magnetic disturbances. Prof. Forbes believed the explanation of recalescence given by himself about 1873 is sufficient to account for the effects observed. This explanation postulates a sudden increase in thermal conductivity about the temperature at which recalescence occurs, which permits the heat from the inside to reach the outside more readily, and thus raise the temperature of the surface. The subsequent reglows observed by Mr. Tomlinson he believes due to convection currents of air. Prof. Rücker suggested that calorimetric experiments might determine which view was the true one, and Prof. Ayrton thought the question might be decided by having two half-round bars nearly in contact at their flat sides, heated up and allowed to cool, and noting whether any sudden change in the bending of each bar (due to unequal temperature at the inner side and outer sides) took place about the critical temperature.—On the rotation of a copper sphere and of copper wire helices when freely suspended in a magnetic field, by Dr. R. C. Shettle. The author exhibited the apparatus with which his experiments "on the supposed new force" were made, the results of which were published in the *Electrician*, vol. xix. Dr. Hofford has recently made similar experiments, using brass disks, and his results seem to point to "diamagnetic non-uniformity" of the disks as the cause of the phenomena he observed.

Linnean Society, December 1.—W. Carruthers, F.R.S., President, in the chair.—There was exhibited for Mr. O. Fraser, of Calcutta, a specimen supposed to be a weather-worn seed of a palm, picked up on the Madras coast. Opinions given at the meeting referred it to the consolidated roe of a fish, doubts being thrown on its vegetable nature.—Sir John Lubbock read a paper, an account of which we have already printed, on the habits of ants, bees, and wasps.—A paper was read by Mr. C. B. Clarke, on a new species of *Panicum* with remarks on the terminology of the Gramineæ.

Geological Society, November 23.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—Note on a New Wealden Iguanodont, and other Dinosaurs, by R. Lydekker.—On the Cae Gwyn Cave, by Prof. T. McKenny Hughes, who contended that the drift outside the cave was a marine deposit *remanié* from older beds of glacial age, but was itself post-glacial and of approximately the same date as the St. Asaph drift. He maintained that the marine drift was deposited before the occupation of the cave by the animals whose remains have been found in it; that at the time of the occupation of the cave the upper opening now seen did not exist, but the animals got in by the other entrance; that against the wall of the cave where it approached most nearly to the face of the cliff, the drift lay thick as we now see it; that by swallow-hole action the cave was first partially filled, and then the thinnest portion of its wall gave way gradually, burying the bone-earth below it, and letting down some of the drift above it, so that some of it now looks as if it might have been laid down by the sea upon pre-existing cave-deposits. The reading of this paper was followed by a discussion, in the course of which Dr. Hicks argued strongly against the author's conclusions.

Mathematical Society, December 8.—Sir J. Cockle, F.R.S., President, in the chair.—Messrs. W. B. Allcock, J. W. Mulcaster, and I. Beyens, Cadiz, were elected members.—The following communications were made:—The algebra of linear partial differential operators, by Capt. Macmahon, R.A.—On a method in the analysis of ternary forms, by J. J. Walker, F.R.S.—Confocal paraboloids, by A. G. Greenhill.—Note on the solution of Green's problem in the case of the sphere, by A. R. Johnson.—Uni-Brocardal triangles and their inscribed triangles, by R. Tucker.

Chemical Society, November 17.—Mr. William Crookes, F.R.S., President, in the chair.—The following papers were read:—Zinc-copper and tin-copper alloys, by A. P. Laurie.—The halogen substituted derivatives of benzalmalonic acid, by C. M. Stuart.—Note on a modification of Traube's capillarimeter, by H. S. Elworthy.—The formation of hyponitrites: a reply, by Edward Divers, F.R.S.—Reply to the foregoing note, by W. R. Dunstan.

Royal Microscopical Society, November 9.—Rev. Dr. Dallinger, F.R.S., President, in the chair.—Mr. E. M. Nelson called attention to a suggestion for supplying a want which many had felt of a really good achromatic single lens or loupe for microscopic purposes, of ½-inch focus. He had found that the want was met by a Seibert No. III. objective, having its adjusting screw removed.—Mr. Nelson further said that, having lately obtained an improvement in optical power, he had been able to do a little more in the matter of resolution, and one of the first objects he had tried was striped muscular fibre. In the early days of microscopy a muscular fibril used to be represented as a series of light and dark bands, the dark band being about twice the diameter of the white band. In 1854 Messrs. Huxley and Busk discovered a dark stripe in the middle of the bright band, and subsequently Hensen placed a similar darker stripe in the middle of the dark band. With his latest optical appliances he had been able to see a faint white stripe on either side of Hensen's dark stripe. He estimated the diameter of the stripes to be all equal. Although he saw evidences of longitudinal breaking up, he could see nothing of Schäfer's "beads."—The third point noticed by Mr. Nelson was Mr. Francis' method of improving definition of such an object as *Amphipleura pellucida* by using the analyzer. He had tested the plan, and found that it did intensify the resolution in a very marked degree.—Mr. Nelson also exhibited and described a new portable microscope made by Messrs. Powell and Lealand from his drawings, and the new photomicrographic camera designed by Mr. C. L. Curties and himself.—Mr. Nelson further exhibited a new eye-piece which he had devised. Having for some time past made a great many experiments with achromatic eye-pieces of double, triple, and other forms, he had not succeeded in producing any combination whose defining power surpassed that of the Huyghenian. The best results were obtained by achromatizing the eye-lens—*i.e.* by making it of a biconvex and a plano-concave, with its convex side towards the eye. The aperture of the diaphragm was reduced until the diameter of the field was equal to that of the Abbe compensating eye piece. This eye-piece, with the achromatized eye-lens, gives the sharpest images he had seen. It works perfectly well with the 24 mm. and 3 mm. Zeiss apochromatic objectives.—Mr. C. R. Beaumont then exhibited and described his new form of slide for observing living organisms, and read a paper on the metamorphoses of *Amœbæ* and *Actinophrys*, in which he claimed to have observed the development of an *Amœba* into an *Actinophrys*, and then into a *Difflugia* and an *Arcella*.—Mr. H. B. Brady's paper, a synopsis of the British recent Foraminifera, was communicated to the meeting by Prof. Bell.

PARIS.

Academy of Sciences, December 5.—M. Janssen in the chair.—Letter to M. Bertrand in connection with his previous note on a theorem relative to errors of observation, by M. Faye. It is pointed out that, if we consider all the combinations of errors, the relations of the sums corresponding to the greatest and smallest of these errors are comprised between the extremes 1 and 3·915. Both of these are infinitely improbable in themselves, while their mean, 2·457, differs little from the number 2·414 given by M. Bertrand.—Reply to M. Mascart on the subject of the deviation of the winds on the synoptical charts, by M. Faye. The author insists that he has nothing to modify in what he has written during the last thirteen years on the descending spiral motion of cyclones. The synoptical charts, which have been multiplied during the last few years, when properly interpreted, are shown to be in no way opposed, but, on the contrary, lend additional support, to his theory.—On the synchronism of accurate time-pieces, and on the distribution of time, by M. A. Cornu. A description is given of the construction and properties of a very simple electric appliance, which is applicable to all kinds of oscillating apparatus, and which

realizes the theoretic conditions under which the problem of synchronism has been solved. This system has already been at work for several years in the École Polytechnique, and has been applied with complete success in the Paris Observatory for the synchronizing of the two clocks in the Department of Longitudes. The problem of the distribution of time with a precision approaching the hundredth part of a second is thus satisfactorily solved. The apparatus is extremely simple and easily regulated, and may be worked with feeble currents.—Remarks in connection with a work entitled "Les Ancêtres de nos Animaux dans les Temps géologiques," presented to the Academy by M. Albert Gaudry. In this work the fossil mammals are tabulated in the ascending order according as they appeared on the earth from the Lower Miocene through all the intervening geological epochs up to the present time. A concluding chapter is devoted to an historic survey of palæontology in the Paris Museum.—On magnetizing by influence, by M. P. Duhem. The questions here discussed are: the quantity of heat liberated in the transformation of a system including magnets, and the heat liberated in the displacement of a magnetic mass.—New nebulæ discovered at the Paris Observatory, by M. G. Bigourdan. The right ascension and polar distance, with miscellaneous remarks, are given of the nebulæ consecutively numbered 51 to 102. Observations are appended on thirteen other nebulæ previously discovered.—On the division of an arc of a circle, by M. A. Pellet. The approximate division of an arc in a given relation is determined by means of rule and compass.—On the expansion of compressed fluids, and especially on that of water, by M. E. H. Amagat. The compressibility and expansion of water, ordinary ether, methylic, ethylic, propylic, and allylic alcohols, acetone, chloride, bromide and iodide of ethyl, sulphide of carbon, and chloride of phosphorus, have been studied between zero and 50°, and from the normal pressure up to 3000 atmospheres. For all except water, which behaves exceptionally, the coefficient of expansion diminishes with increased pressure, the decrease being still very perceptible at the highest point. The coefficient of water increases very rapidly at first, but afterwards diminishes gradually, disappearing altogether towards 2500 atmospheres.—On a new method of quantitative analysis for carbonic acid in solution, by M. Léo Vignon. By the process here described the presence may be detected of 1 cubic centimetre of carbonic acid in 1 litre of water.—Influence of natural or superinduced sleep on the activity of the respiratory combustions, by M. L. de Saint-Martin. It is shown that, apart from the state of fasting, natural sleep lowers by about one-fifth the quantity of carbonic acid exhaled, and by only one-tenth the quantity of oxygen absorbed; also, that in sleep brought about by morphine the proportion exhaled falls to one-half, and in sleep caused by chloral or chloroform to one-third, of the quantity exhaled during the same lapse of time in the normal state.—On the absence of microbes in the human breath, by MM. J. Straus and W. Dubreuilh. These researches fully confirm the conclusions already arrived at by Lister and Tyndall regarding the freedom of exhaled breath from the presence of pulmonary or other microbes.

Berlin.

Physical Society, Nov. 11.—Prof. von Helmholtz, President, in the chair. —Dr. Weinstein spoke on the determination of the electrical resistance of tubes of mercury. He employs two methods for measuring the length of the tubes, one in which the tube is completely filled with mercury, the other in which it is only partially filled, and in which the convexity of the ends of the column of mercury is taken into account. The first method is the more exact, but is less simple; the difference between the methods is small. The measurement of the diameter of the tube is of great importance, and is made under the assumption that the tube is either a cylinder or a cone; the latter is the more correct assumption when the tube is long, and necessitates calibrational corrections, for which Dr. Weinstein deduced the formulæ. Taking into account the want of accuracy in the constants involved in the above, he considers it far better to determine the volume from the heights of the capillary rise of fluids in the tube.—Prof. Pictet, who was present as a guest, gave a detailed account of the experiments he has made with his ice-machines, which have led to results which do not agree with Carnot's theories as far as the second law of thermodynamics is concerned. He described the action of a perfect ice-machine, consisting of a refrigerator, pump, and condenser. In the refrigerator a quantity of heat is taken from the salt-water bath surrounding it, which causes some of the fluid to evaporate; this vapour, at the temperature of the surroundings, passes unchanged into the pump, where it is compressed, and forced, at high pressure, into the condenser, where it at once becomes a liquid, and gives up all its heat to the surroundings. This condensed fluid then flows back to the refrigerator. In a real machine of finitely small dimensions, the temperature in the refrigerator falls, the vapour meets with resistance in passing over into the pump, and in passing from the latter into the condenser, and there is a fall of temperature as the heat passes out into the surroundings from the liquid formed in the condenser. The speaker determined by careful experiments the tension of the vapour with which he worked between − 20° C. and + 30° C., and then he measured the temperatures in the several parts of the working machine by means of manometers which registered the pressures in the several parts, and from this he arrived at the result stated above. The measurements were made when the pump was working both rapidly and slowly, and also when it was stopped. Prof. von Helmholtz drew attention to two sources of error which cannot be avoided in Prof. Pictet's experiments, and which might account for the results obtained being in opposition to Carnot's law. In the first place, the vapour might contain air; this would influence the pressure existing in the machine, without itself undergoing any condensation, and hence it is impossible to determine the temperature of the vapour accurately from measurements of its pressure. The second source of error is, however, still more important. In Pictet's ice-machines, the liquid used is a mixture of liquefied carbonic acid gas and sulphur dioxide. From such a mixture as this the more volatile carbonic acid gas must pass over into the refrigerator in larger quantities than the less volatile sulphur dioxide. Hence both the vapour and the liquid resulting from its condensation have a composition markedly different from that of the original liquid. Now the calculations are made on the assumption that the liquid undergoes no change of composition, hence the temperatures determined from the pressures cannot correspond to those really existing in the several parts of the apparatus. Prof. Helmholtz hence considers that the temperatures in the refrigerator and condenser should be measured with thermometers, in which case only it would be possible to test the truth of Carnot's laws on the basis of the heat-values obtained in the experiments.

November 25.—Prof. von Helmholtz, President, in the chair.—Dr. Stapff spoke on his measurements of the temperature of the earth in South Africa. From his observations on the temperature in the St. Gothard Tunnel, and a comparison of these with the temperatures observed at the earth's surface, he had deduced an empirical formula for the difference of temperature between the air and the earth: according to this formula, the difference is greater the lower the temperature of the air, and disappears when the temperature of the air rises to 11° C. It hence became a matter of interest to determine whether the difference is negative when the temperature of the air is very high. Dr. Stapff had made use of a sojourn in South Africa, near Whale Bay, while engaged in geological studies, for the purpose of carrying out observations on the temperature of the earth. The district in which he worked lies in the Tropic of Capricorn, about in the same meridian as Berlin, and the soil is sandy with a current of water running beneath it towards the sea. The observations were made in borings with English mining-thermometers, which were allowed to remain about twelve hours at the depth where the temperature was to be determined, thus insuring that they had taken up the temperature of the surroundings. The measurement of the temperature at the earth's surface presented very great difficulties, and was only rendered possible by covering the bulb of the thermometer with a layer of sand 5 cm. thick. The greatest depth at which the temperature of the earth was measured was 17 metres. From the determinations thus made it appeared that the temperature diminished down to that depth, a result undoubtedly dependent upon the fact that the measurements were made during the hottest time of the year. The speaker found that the depth down to which the temperature varies with that of the air is about 13·6 metres, the temperature at this depth being about 25° C. The changes in temperature of the earth were very considerable, greater than those of the air, amounting in the sand to some 30° to 40° C. His measurements, however, did not show any negative value for the difference in temperature of the air and earth.—Dr. Sieg gave an account of his experiments for the determination of the capillary constants

for large drops and bubbles. On account of the marked divergence in the results obtained by Quincke as compared with the older measurements, the speaker was led to subject Quincke's method to a detailed examination. He found that the determination of the height of the drop is exact, but that the measurement of its width by means of the micrometer is too uncertain. Instead of this method, he therefore employed the reflection of a flame from the side of the drop in order to determine the convexity of the same, and using Poisson's method of calculating the results instead of that of Quincke, he obtained as the value of the capillary constant, not 54 as given by Quincke, but 44·5, thus agreeing with the older determinations. The mercury was purified and examined by Quincke's method. In addition Dr. Sieg has determined the capillary constants for water, alcohol, oils, and a series of salt-solutions of varying concentrations. One result may be mentioned as shown by these experiments, that the capillary constant of mercury sinks to forty-two when the mercury has stood for some time, and that the same fall is observed if the mercury is put to earth; the constant is also altered if the drop is electrified or is impure. With salt-solutions the constants were dependent upon both composition and concentration. Water was also found to be very sensitive to the presence of any impurities, and while the solution of salts in water was not found to alter its capillary constants, the solution of gases produced a very appreciable alteration

Physiological Society, November 18.—Prof. du Bois Reymond, President, in the chair.—After the statutory election of the Council, Dr. Benda demonstrated a malformation as occurring in a three-months' embryo, in which two strongly marked prominences on the lower portion of the forehead gave to its countenance a curiously contemplative appearance.—Prof. Kossel next spoke on adenin. The most recent researches on the importance of the nucleus to the life of the cell, especially the knowledge that when unicellular organisms are artificially cut into pieces only those parts exhibit a complete regeneration which contain a portion of the nucleus, and the importance of the nucleus in impregnation have given an increased importance to the chemistry of the nucleus. Among the chemical substances which compose the nucleus, adenin, which has recently been discovered by the speaker, appears to possess a special importance, since, on account of its composition, $C_5H_5N_5$, it belongs to the cyanic group of bodies. This substance was obtained from tea-leaves in large quantities, and from it a series of compounds were obtained, which were exhibited as extremely fine preparations; namely, the salts with hydrochloric, sulphuric, and nitric acids, as also some compounds with platinum. Adenin was found to be extremely resistant to feebly oxidizing agents, but on the other hand to be easily acted upon by reducing agents. The substances which are produced by these means were not very well characterized from a chemical point of view. The speaker however thinks that, owing to the ease with which it can be reduced, adenin plays an extremely important part in the physiological action of the nucleus. When adenin is reduced in presence of oxygen, a brownish-black substance is obtained, which appears to be identical with the azocuminic acid which is produced when hydrocyanic acid is exposed to the air for a long time. In conclusion, Prof. Kossel pointed out that adenin makes its appearance in large quantities under certain pathological conditions, and that he has succeeded in detecting it in the urine of persons suffering from leuchæmia. —Dr. Rawitz gave an account of his investigations on mucous cells in Invertebrates. He has found in the mantle of mussels goblet-cells, of which some are small with a large central nucleus and granular protoplasm; others are large with a small central nucleus, the rest of the cell-contents being uniform in appearance; and others again are large, with a small nucleus situated at the base of the cell, the protoplasm having oily granules scattered throughout itself. This last kind of cell allows the oily granules and mucous contents to pass out at the apex of the cell into the surrounding water. A careful investigation has shown that the above three different kinds of cells are merely different stages in the secretory activity of the mucous cells, and that during this activity the cell-contents not only undergo a change of minute structure, but also of chemical composition, the latter being evidenced by the changed reactions which they give with staining agents. During secretion the cell itself is not broken down, but only a portion of its protoplasm is excreted, in the form of oily drops and mucous threads, the nucleus remaining intact. Dr. Rawitz considers that special importance must be assigned to the nucleus in connection with the nutrition of the cell, as during the secretory activity of the cell it undergoes changes not only in its shape, but in its behaviour towards taining reagents.

THURSDAY, DECEMBER 22, 1887.

THE STAR OF BETHLEHEM.

THE fact that a little more than a month ago the planet Venus arrived at its maximum brilliancy when to the west of the sun, and therefore when the planet rises before the sun, has given rise to a flood of superstitious fears in this country, only to be equalled in modern times by that which the members of the Eclipse Expedition observed in Grenada last year, and chronicled in these columns, as having been met with among the semi-civilized inhabitants of that island.

In spite of School Boards and all the present stock-in-trade of elementary education, perhaps partly because that elementary education deals so little with natural science; and because before School Boards so many children scarcely went to school at all, the planet Venus, one of the most stable and the most brilliant member of the solar system, is being regarded as a second appearance of the star of Bethlehem!

This being the idea which ignorance has conjured up, superstition next comes in to bear her part, and hence very naturally all sorts of woe and desolations, the end of this world being naturally included among them, have been predicted, and in some places a considerable amount of alarm has really arisen. Nor is this all: thousands of people who ought to be able to look up pocket-books and almanacs for themselves have been for the last month pestering everybody who is known to possess a telescope for information on the subject.

We think it, therefore, worth while to refer to this subject, for we have in this ignorant fright an additional reason, which it may be worth while to dwell upon, why the young population of a country like England should not be allowed to grow up without some knowledge, however slight, of the natural phenomena which are always being unfolded around them—phenomena which will always delight, instruct, and interest them if understood, but which will be apt to cause alarm so long as they are shrouded in mystery.

As before stated, the brilliant body in the east which is the innocent cause of all the alarm is nothing but the planet Venus near that position in her orbit in which she can send the greatest amount of light towards us.

If our youngest reader will place a candle in the middle of a table, and support a little ball some six or eight inches away from the candle, on the same level, and then retire some little distance away, to represent a spectator on the earth, the reason why Venus sometimes appears to the right or to the west of the sun and at other times to the east or left of it will be at once clear to him, if the ball be imagined to go round the candle in a direction contrary to that of the hands of a watch. Further, the fact that when the ball is on the other side of the candle it is further away, and therefore appears smaller than it is when exactly between the candle and the spectator, will give a reason why in neither of these cases will the maximum brilliancy be observed, because in one case the planet is as far away as it can be, and in the other, though the planet is as near to us as it can be, it has its dark side turned towards us; for it must be clearly understood that Venus, like the earth, receives its light from the sun, represented in our experiment by the candle; and when the spectator is on one side of the little ball, representing Venus, and the candle is on the other, naturally the non-illuminated side of the ball alone is turned towards the spectator. The period of maximum brilliancy will be when the planet is to the right or left of a line adjoining the spectator and the candle, and nearer the observer than the candle is. When the planet is to the right of this line, and therefore to the westward of it, speaking celestially, the planet must set before the sun, and therefore rise before the sun: it will be a morning star. On the other hand, when to the left of it, it must set after the sun, and therefore it will be visible as an evening star; and because it sets after the sun it will rise after it, and therefore be invisible as a morning star on account of the overpowering light of the sun. We might apologize to the readers of NATURE for referring to such elementary astronomy as this, were it not quite possible that many of them will have an opportunity, if the scare continues, of showing several young minds how to make the experiment for themselves.

The accompanying diagram will show the positions of Venus and the earth for the last few months, and will

Venus as "Evening Star."

Venus as "Morning Star."

Diagram showing the paths of the Earth and Venus from July 13 to December 1, 1887, with the points of maximum brilliancy on August 16 and October 28. Synodic period of Venus, 583·92 mean solar days.

indicate why it was at its brightest *as a morning star*, on October 28, and *as an evening star* on August 16.

It will be in the memory of some of our readers that on the appearance of the new star observed by Tycho Brahe in 1572 the general opinion was that that also was the star of Bethlehem returned. It mattered little to the vulgar that the latter was called "the star in the East," and that the new star was nearly in the zenith, and at about the same time of the year (November).

A reference to Grant's admirable history of physical astronomy will show us that such new stars were also recorded in 130, 390, 945, and 1264. The authority for these statements is Cyprian Leowitz, whose work was published in 1573. Although his statements have been discredited, there is nothing improbable in them. The "new star" of which we have heard the most, because there was a man living who was capable of chronicling and more or less understanding the phenomenon, was that to which we have referred above as having appeared in the year 1572. This was carefully watched by Tycho

Brahe. It suddenly appeared brighter than any of the stars, and brighter than Jupiter, though not brighter than Venus. This star remained visible for nearly two years. Its colour changed as it grew dimmer: first it was white, then yellow, then red, and finally, according to the record, exhibited a leaden hue like the planet Saturn. Tycho Brahe imagined it generated from the ethereal substance of which he held the Milky Way to be composed, and when it disappeared it was thought to have dissolved spontaneously from some internal cause.

It is not a gratifying thing to find, when we come to inquire further into the state of public feeling at the time when Tycho's star appeared, that after all we have advanced very little beyond the sixteenth century in matters relating to superstition. The world was to end in 1532, according to Simon Goulart, because a mountain in Assyria had been seen to open, and exposed to the gaze of those present a scroll with letters written in Greek stating that the end of the world was at hand.

Goulart was followed by a famous astrologer, Leovitius, who put on the date to 1584; and Gayon reports that the fright at that time was almost universal, and the churches would not hold those who sought shelter in them.

This end of the world mania was not confined to the unlearned, for a famous mathematician, Stoffler, who was actually engaged on the reform of the calendar undertaken by the Council of Constance, put down the end for February 1524. According to him, the end was to be by water and not by fire, and the basis of his prediction was that Saturn, Jupiter, and Mars would then be together in the sign Pisces. It was a rare time for the boat-builders, for many "arks" were built; a doctor of Toulouse, named Auriol, making himself immortal by building the biggest.

Stoffler and Regiomontanus were not, however, discouraged by the fact that not a drop of rain fell during the whole of that month in Central Europe: they merely put the date on to 1588.

It must be remembered that in those days of unusual superstition these predictions were carried broadcast through the land, and it was the consternation of the ignorant which caused everybody to believe that Tycho's star, which appeared in 1572, was really the star of Bethlehem, returned to announce the second coming of Christ.

But as a matter of fact this star of Tycho's is really connected with the present excitement, and again the idea of the return of the star of Bethlehem has been associated with it—although the year 1572 passed off quite quietly, and the planet still survives—for the following reasons. The star appeared between the constellations of Cassiopeia and Cepheus—that is, in the same part of the heavens in which in former times, in 945 and 1264, similar appearances had been recorded. Argelander, who inquired into the matter, found a 10½-magnitude star catalogued by D'Arrest, but seen some years before, when the same part of the heavens (R.A. 4h. 19m. 58s., Decl. + 63° 23′ 55″) was under scrutiny. It was suggested, therefore, that the star in question might be a variable one with a period of 314 years: this would very closely account for appearances in the years 0, 945, 1264, 1672, and 1887! and if it were really the star of Bethlehem, it would be naturally seen about Christmas-time. Nothing is more curious than to watch how a piece of scientific knowledge has thus settled down to form a nucleus for a haze of sensational nonsense.

But it is not impossible that, after all, we are really again in presence of the star of Bethlehem; for if we read the account in St. Matthew, and assume that some celestial body is really alluded to, and not a miraculous appearance similar to those recorded by St. Luke (chapter ii. 8–15), then it would seem that Venus, as she has been seen lately—that is, at her maximum brightness—will do as well as any other, and there is no necessity to assume either a "new star," or a comet, as giving rise to the phenomena recorded.

We give that part of the narrative which chiefly concerns us, and it is necessary to bear in mind that Bethlehem lies nearly due south of Jerusalem, and is about five miles distant.

". . . There came wise men *from the east* to Jerusalem, saying, . . . we have seen his star *in the east*. . . . When they had heard the king, they departed [to Bethlehem]; and, lo, the star, which they saw [had seen] in the east, went before them, till it came and stood over where the young child was. When they saw the star, they rejoiced."

The fact that the star was stated to be seen "in the East" would imply that it was not seen anywhere else. This is best explained by supposing a *morning* observation of a body soon rendered invisible by the light of the sun. A star seen in the East at evening would be visible all night, and could no longer be properly designated as a "star in the East." This is against the views which have been held and supported by Kepler, to the effect that a conjunction of superior planets was in question; and indeed they have already been demolished by Prof. Pritchard.

If we assume that the star was Venus at maximum brightness seen in the East in the morning, and that it rose, say, two hours before the sun, it would be about south at 10 a.m. It would seem not improbable that the journey to Bethlehem should be made before noon. The gathering of the priests and scribes would probably last till sundown, and it would be natural that the journey should be undertaken next morning. Journeys in the East are not generally now, and were probably not then, undertaken in the evening. The latter part of the extract indicates that the "wise men" did not see the star till they got to Bethlehem, and that the statement that "the star went before them" is rather an attempted explanation of its change of place than a reference to any actual observation.

The simple facts, then, seem to be that the "wise men"—no wiser, it would appear, than the average Englishman of the present day, in astronomical matters—being struck by the exceeding brilliancy of Venus, which they did not recognize, felt sufficient interest in it, or, more probably, were so soundly frightened at it, that they went to the nearest important town, Jerusalem, to find out something about it. It has been assumed that the Magi came from a *great* distance, but there is nothing to justify this, apparently; and if we go beyond the record at all we may as well accept them at once as Melchior, Balthazar, and Jasper, the kings respectively of Nubia, Chaldea, and Tarshish, whose bones are supposed to be at Cologne, though their connection with the Biblical narrative is not clear, as it

is not on record where these personages joined company before they set out *westwards* for Jerusalem.

As comets long afterwards were supposed to presage disaster, so the star may have been regarded as an indication of the approaching death of King Herod. This would start the question as to his successor, whom the "wise men" would desire to stand well with, or to "worship." With what happened at Jerusalem we have nothing to do. On approaching Bethlehem about noon, they again recognized the star over the town, as Venus would be at that time, on the supposition that the "star in the East" which they had first seen was really that planet.

Another point connected with this matter relates to the question of new stars. Supposing there were a new star in the east, why should the population be affrighted? The records of astronomy, as we have seen, tell of a considerable number of such stars, and during the last few years we have been favoured with our fair share of such appearances, and yet the world is none the worse for them. The view which has recently been put forward, with an amount of evidence to back it which almost puts it beyond question, is that in new stars we see only such phenomena as we must expect; we see the result of no unnatural dealings with the regulated order of the universe, but simply the collisions of swarms of meteorites, these meteorites being not only not in our own system, but lost, it may be, in the very depths of space. Why should such a thing as this affright us? It is simply what happens at a level crossing when a train runs into a cart, and it does not seem likely that such an ordinary piece of mechanism as this would be chosen as a means of frightening or ringing the death-knell of a world.

Modern science, while thus abolishing mystery from the skies, is only enhancing the majesty of all created things. The universal law and order are more clearly seen in every great advance; and yet, with a population so superstitious that the least uncomprehended thing affrights them, our statesmen are still on the side of ignorance, and hinder rather than aid the introduction of science into our schools.

THE MICROSCOPE.

The Microscope in Theory and Practice. Translated from the German of Prof. Carl Naegeli and Prof. S. Schwendener. (London: Swan Sonnenschein and Co., 1887.)

THIS book opens to English readers an entirely new page in microscopical literature. It leads the way in supplying a want which every thorough microscopist has realized for the last twenty years. In a complete form this treatise has been accessible to the German reader for at least ten years. The absence of it, or an equivalent, in the English language has been a most serious drawback to the advancement of the highest optical work in English microscopes. In optical manipulation, the English optician at his best proves not only equal to any in the world, but, in the highest class of work, has shown lately that he takes a foremost place. But with no attempt on the part of English mathematicians and microscopists to become masters and expounders of the theory of the microscope and of microscopic vision, the practical optician can make no real advance. English "stands," and those made in America on English models, are of exquisite construction, and are quite equal to our present necessities; but, for all the great advances and improvements that have been made in *English* object-glasses during the last fifteen years, we are, for all practical purposes, primarily indebted to Germany. And this is readily explained by the fact that the German specialists have made a systematic and persistent study of the theory of the microscope.

It is not forgotten that it was to the suggestion of Mr. J. W. Stephenson that we are indebted for the invaluable improvements that belong to the homogeneous system of lenses.[1] But, without doubt, it was on account of the insight which a study of the theory of microscopic vision brought with it, that Mr. Stephenson perceived at once the advantages of great numerical aperture, and the new way to obtain it. Moreover, it is certain that Prof. Abbe was approaching this very method of employing lenses, though from another point, and not in so direct a way. It would have been shortly reached by him there can be but little question; but when it was reached, what did a constant, enthusiastic, and laborious study of the theory of the microscope carry with it? A perception, that with glass of greater range of refractive and dispersive indices than any we possessed, we might not only secure great numerical apertures, but secure them devoid of all colour; that we could not only annul the primary, but also the secondary and tertiary, spectra. It need not surprise us then, that, in a country where such splendid theoretical and mathematical work had been done by experts on the principles of microscopic lenses and the laws of their construction and use, even the Government should be convinced that the time to aid the optical expert had come; that theory had demonstrated the practical possibility of a great improvement in the construction of lenses. The sum of £6000 was granted by the German Government to Abbe and his collaborateurs, and with, as we have reason to believe, an equivalent outlay on Abbe's own part, the new glass was prepared; and the new Apochromatic lenses with their systems of compensating eye-pieces devised.

It is in no spirit of boast, but rather in a spirit of humiliation and regret, that we say that we have examined many of these apochromatic objectives of all the powers made in Germany, and we have examined all the principal ones that have, since the new glass has reached London, been made there; and we are bound to say that the English work, based on the principles laid down by Abbe, is so fine as to make the regret immeasurably keener that English microscopical literature has been for all these years a blank, for practical purposes, on the theory and principles of optical construction, and on the theory of microscopical observation and interpretation. Such a paper as that of Prof. G. G. Stokes, P.R.S., on the question of a theoretical limit to the apertures of microscopic objectives (Journ. R.M.S., vol. i. p. 139) from its very loneliness only gives emphasis and point to our contention. Those who have any doubt of the full force of what we are here contending for, have only to compare a dry $\frac{1}{6}$-inch objective, say of twenty-five years ago, made

[1] "On a Large-angled Immersion Objective, without Adjustment Collar with some Observations on Numerical Aperture," by J. W. Stephenson F.R.A.S. (Journ. Roy. Micros. Soc. vol. i. p. 51).

by the best makers in London, with a well-chosen water-immersion of ten years ago; and both these with a recent homogeneous glass of the same power with a numerical aperture of 1·5. Or still better, a dry $\frac{1}{50}$-inch objective, of the same date and the same makers, of numerical aperture 0·98, with a water-immersion lens of the same power of say ten years ago, having an aperture of 1·04, and a recent homogeneous $\frac{1}{50}$-inch, with a numerical aperture of 1·38. Still more strikingly, let the same observations be made with a dry $\frac{1}{12}$-inch objective of twenty years ago, with a numerical aperture of 0·99, and a homogeneous lens of the same power, with numerical aperture 1·5; and, finally, both these with an apochromatic objective of the same power by the same London makers and an aperture of 1·40. We venture to say, to histologist, bacteriologist, diatomist, and all other serious workers with the microscope, that there can be no proper comparison of the results; or, rather, the comparison is odious indeed for the oldest, and even the elder, lenses.

But, as we have stated, it is to Germany we are indebted for the *knowledge* out of which, alone, these improvements could have arisen. In spite of the length and abundance of English treatises on the microscope, it has never been part of the scope of the respective authors to do other than make the scantiest reference to the principles of the microscope; and nothing is found that will elucidate the theory of the construction of objectives, and eye-pieces, and the possible and real relations of each to the other. There is nothing to be found indeed in our language, except in the invaluable translations published in the successive Journals of the Royal Microscopical Society, which discusses the phenomena of diffraction, of polarization, of the principles of the true interpretation of microscopical images, and the theory of work with the microscope. English workers with high powers have discovered painfully where their lenses during many years were at fault; they could show our opticians *what* they wanted; but it has been only as the result of the laborious mastery of the theory of lens-construction by German investigators, with Abbe at their head, that the English worker has been able to get his wants, in object-glasses and eye-pieces, supplied.

But like all advances in insight and analytical power, these very improvements, so welcome and so helpful to searchers in many important branches of science, only open up the horizon of the unknown more fully; and the very knowledge we get, through the inestimable improvements, only reveals new difficulties; and again creates optical wants. It is, then, with pleasure indeed that we hail this excellent translation of Naegeli's work on the theory and practice of the microscope The book has long been announced, and many have looked, year after year, eagerly for its coming. But a series of untoward circumstances have combined to make the delay inevitable. The translation was begun some ten years since by Mr. Frank Crisp, the Secretary of the Royal Microscopical Society, purely in the interests of microscopy in England. He wished to fill the blank in the microscopical literature of the country, which had, in fact, become almost a dishonour to us. This book of Naegeli and Schwendener is a thorough treatise on the theory of the microscope, giving a detailed theoretical exposition of the construction of objectives, eye-pieces, &c., with analytical determination of the path of the rays in refracting systems; discussing exhaustively chromatic and spherical aberration; the influence of the cover-glass; the flatness of the field of view; the centering of systems of lenses; the importance of aperture, with a discussion of the diffractional action of the aperture of the lenses; and the question of illumination.

With equal care and thoroughness there is a discussion of the testing of the microscope, in all its branches, which cannot but make the student conversant with every essential point in the construction of the instrument; and an absolutely invaluable monograph on the theory of microscopic observation, which no one attempting to publish results of any importance dare leave unread or even unstudied. The phenomena of polarization receive equal care in treatment and must prove of the utmost value.

To put such a book within the reach of English readers, Mr. Crisp rightly felt, would be to give the needed stimulus to English microscopical observation: it would put them on the same horizon with German specialists. But the first impediment to its appearing in print was, that Mr. Crisp was compelled, by the weight of other claims upon his time, to relinquish the task of preparing the translation for the press when only eighty pages were in type; and a large lapse of time ensued before the labour was at length resumed by Mr. John Mayall, Jun., one of the editors of the Journal of the Royal Microscopical Society. But, beyond this, when Mr. Mayall had done his work and the printing of the work was complete, a fire destroyed the premises of the printer and all but a small portion of the type was wholly lost. The present issue is therefore an entire reprint.

There is but one point that we can see in the book, as it now stands, that need call for the slightest reflection: it is that the authors adopt, and discuss at considerable length, a method of testing the resolving power of objectives which has had—in another connection—the honour of a mathematical refutation by the highest living authority on microscopical optics, Prof. E. Abbe, of Jena. This method consists of viewing, with the objective to be tested, what were assumed to be "miniatured images" of a network of wire gauze produced by minute globules of oil and other matters, which images were supposed to be reduced to the "limit of discrimination" by simply distancing the wire gauze from the oil globule. Prof. Abbe's demonstration (*vide* Journ. Royal Micros. Soc. 1882, pp. 693-96) of the fallacy of this method proves that the combination of a microscope with a minute oil globule, or its equivalent, for viewing a distant object—whether wire gauze, or a so-called "double star" arrangement as advocated by Dr. Royston Piggott—serves no purpose whatever in determining the limit of the resolving power of the objective; but merely produces a very low-power telescope; the power of which may easily be so low, indeed, that the eye fails to differentiate, or even to perceive, the image!

The adoption of this fallacious mode of reasoning, however, amounts only to a blemish in an otherwise most excellent work; and with the publication and accessibility of Abbe's correction can do but little harm.

It would have given a still higher value to the book if the chapters devoted to an exposition of Prof. Abbe's

views on the formation of images in the microscope had received the advantage of his personal and later revision; but it is none the less due to the authors to acknowledge the credit that is justly theirs, for the very early recognition of the value of his investigations; and for the earnest manner in which they endeavoured to embody those investigations in a popular text-book at a date (1877) when hardly more than the barest outlines of the subject had been published by Prof. Abbe himself.

We note that the authors give the preference to daylight over lamp-light, believing that it exerts less strain upon the eye. We suspect that the majority of English observers, especially at continuous work, and with high powers, will be inclined to reverse this judgment. Extremely white and intense light can be obtained from good modern lamps, and, unlike daylight, it is unvarying, devoid of caprice, and easy of manipulation. But this is a matter, perhaps, in some sense subjective, and not of vital moment.

The world of science generally and of microscopical science in particular, is deeply indebted to Mr. Crisp for initiating this translation, which, we have taken pains to find, is most carefully done; and to Mr. Mayall for his part of the laborious undertaking. We can only hope, in the interests of English and American science, that it will find a large circle of careful readers on both sides of the Atlantic; and we warmly concur in the hope expressed in the preface, "that the volume may be supplemented before long by an English version of the further researches in microscopical optics by Prof. Abbe, of Jena, which have extended so much our knowledge of the matters dealt with in Naegeli and Schwendener's work."

W. H. DALLINGER.

THE CRUISE OF THE "DIJUMPHNA."

The Cruise of the "Dijumphna." With Reports of the Zoological and Botanical Results of the Voyage. By R. Bergh, J. Deichmann Brandt, J. Collin, H. Hansen, T. Holm, C. Jensen, G. Levinsen, C. Lütken, L. K. Rosenvinge, M. Traustedt, and N. Wille. (Copenhagen, 1887.)

THE Danish Arctic Expedition of 1882-83 owes its initiative to its able commander, Lieut. Hovgaard, of the Danish Navy. This enterprising officer, whose practical experience of Arctic navigation gave great weight to his opinions on the subject, had early in 1882 published a pamphlet, entitled "Suggestions for a Danish Polar Expedition," in which he advocated his own theories regarding the distribution of land and water in the Arctic regions, and the feasibility of finding some hitherto untried route for circumpolar exploration.

In response to his appeal for means to test the accuracy of his opinions, a private individual, Herr Gamél, of Copenhagen, placed at his disposal a screw-steamer, since known as the *Dijumphna*, whose equipment for Polar explorations and scientific observations was supplemented at the expense of the Danish Ministry of Marine.

Thus well prepared, the Expedition left the Copenhagen Roads, July 18, 1882, but unfortunately the *Dijumphna* early encountered ice, which was found to be so dense south of Cape Tschernui Noss that it was only after a delay of more than four weeks off the south-west coasts of Nova Zembla, that an entrance could be made into the Sea of Kara, where, in accordance with Hovgaard's anticipations, the water was clear. The hopes of success to which this fact gave rise proved, however, delusive, for the ice began to re-form so rapidly that, within a few days of their passage into the Kara Sea, it had become apparent that the *Dijumphna* was fast bound for the coming winter; and it was only after nearly a twelvemonth's detention that the ice began to loosen, when the westerly trend of the drifts carried the ship, in the August of 1883, back towards the entrance of the Sea of Kara. With a broken screw and failing supplies, there was no alternative but to renounce all hope of advancing further east, and, accordingly, by help of sails the *Dijumphna* began its homeward voyage, which was so retarded by ice-drifts and storms that the harbour of Copenhagen was not reached till December 3, 1883.

In the course of the winter the sun remained below the horizon from November 20 to January 22, the temperature at the latter date falling as low as $-47^{\circ}\cdot9$ C.; while there was constant danger of being crushed in the ice, or carried with moving drifts on the shore. Yet, notwithstanding these drawbacks, the trawl and dredge were diligently used at 190 different stations, ten of which were in the Jugor Schar and in Olenje Sound, off the south-west coast of Nova Zembla. Most of the deep-sea soundings were carried on in the Sea of Kara, between 69° 42′ N. lat., 64° 45′ E. long., and 71° 46′ N. lat., 65° 14′ E. long., within which limits the ship was moved forward and backward by the ice-drifts. This ground proved specially rich, and Herr Holm, the efficient naturalist of the Expedition, was able to bring home an exceptionally large number of well-preserved botanical and animal collections, which now form a valuable addition to the contents of the Danish National Museum, to which they have been generously ceded by Herr Gamél, the owner of the *Dijumphna*.

Herr Holm's report of the flora of Nova Zembla, which he examined at twelve distinct localities during the *Dijumphna's* long detention off the coast, confirms the statement of Von Baer as to the abundance of vegetation on the tundras, but he differs from him in regard to the mode in which plants found their way into these high latitudes. According to Von Baer, to whose report of his scientific mission, undertaken for the Russian Government in 1837, we are indebted for our first acquaintance with the Nova Zembla flora, its plants have all been stranded from neighbouring shores through the agency of drifting ice. Herr Holm, on the other hand, believes that a few forms may be survivals from pre-glacial periods, but that the presence of the majority is due partly to the agency of birds, of which large numbers, more especially Tringa and other waders, frequent the shores, and partly to the winds, and to ice-drifts. Insects are too rare to affect the question of plant-propagation, and his observations—that most plants on the tundras have the corolla directed upwards, while pendent or drooping forms are very rare, and that the majority are scentless, and of one uniform colour—appear to favour these views; although it is possible that the existing flora may also to some extent be due to self-fertilization.

The general appearance of the tundras is that of a slightly irregular plain, the irregularities being due to the tuft-like character of the patches of vegetation, which are separated by pools and streams of melting ice, from which innumerable mosses emerge. When closely examined, these tufts are found to consist of plants dwarfed out of all resemblance to their more southern congeners; thus, *Salix polaris* never rises more than 2 inches in height, although the number of its annual layers of growth—consisting only of five to six cells—may indicate an age of thirty years. Considered generally, the Nova Zemblan flora consists of twenty-eight families of Dicotyledons, four Monocotyledons, and four Cryptogams. Among the Phanerogamæ the most largely represented are the Gramineæ, of which thirty-one species have been distinguished. Curiously enough, it is found that contrary to their habits in more southern regions the Dicotyledons flower earlier than Monocotyledons, which contribute the larger proportion of the flora of the tundras, both as regards species and individuals. The number of new phanerogamic forms derived from the *Dijumphna* Expedition scarcely exceeds a dozen, and of these the most interesting are *Salix arctica*, *Glyceria tenella*, *Potentilla emarginata*, and three species of Carex, viz. *C. incurva*, *lagopina*, and *hyperborea*. As many as eight species of Saxifraga were met with, while Phaca is the only representative of Papilionaceous plants.

Special interest attaches to the collection of mosses brought home by Herr Holm, and examined by Herr C. Jensen, whose report shows that among the entire sixty-four species, of which fifty-one belonged to the tundras and the cliffs of Nova Zembla, three were genuine Arctic forms, viz. *Voitia hyperborea*, *Bryum obtusifolium*, and *Amblystegium brevifolium*. In Wulfberg's report of the mosses collected in the Norwegian Expedition of 1872, which is the only other notice of the Arctic Cryptogams, only twenty-four are noted, so that we owe our acquaintance with forty species to the industry of the *Dijumphna's* collectors. Herr Holm was equally fortunate in finding hitherto unrecorded fresh-water Algæ in South-West Nova Zembla; but in regard to the marine Algæ he has little to record that had not been previously made known, while he corroborates the statements of earlier explorers as to the luxuriant profusion of gigantic Laminariæ, which fringe the coasts at a depth of from 1 to 5 fathoms, where he obtained fronds of *Alaria esculenta* more than 15 feet long.

In passing to the consideration of the zoological results of the *Dijumphna* Expedition, we must admit that excepting in regard to the Invertebrata, for whose capture no better hunting-grounds than such Laminarian forests can be wished for, the results are negative rather than positive. Of the higher marine Vertebrates only *Phoca fœtida* and *Odobænus rosmarus* were seen. A few foxes were noted, and a young she-bear was shot, which was the only specimen of big game attainable. Fishes, mostly belonging to Icelus, Lycodes, and Liparis, were taken so sparsely in from 49 to 106 fathoms that only twenty-eight out of the entire 190 trawls yielded a single specimen. In regard to the Invertebrates the yields were, however, enormous, showing an astonishing abundance of animal life in the Arctic waters. Thus, one haul brought up 928 specimens of *Glyptonotus entomon*, 300 of *G. Sabini*, besides enormous numbers of Alcyonidæ, Sponges, Actinias, and other Polyp forms. Nor was this an exceptional case. In the Sea of Kara the Echinodermata ranked first as to individual numbers, but Crustaceæ as to species, eighty-two of the latter having been determined, of which ten belonged to the family of the Pycnogonidæ. Among Crustaceans generally, seventeen new species have been established by Herr Hansen, whose report supplies much interesting and novel information in regard to the structure of the foot-jaws of the Isopoda, of which he proposes to treat more in detail in a special monograph on the buccal organs and antennæ of the most important Crustacean types.

Gastropods and Annelids were of rare occurrence, and only one genus of Cephalopods, Rossia, was observed. The Simple Ascidians, which have been carefully studied and reported on by Dr. Traustedt, have relatively speaking yielded many novel results, while five of the eight species collected are new, of which the most interesting are *Phallusia dijumphniana* and *P. glacialis*.

The volume in which the various reports on the *Dijumphna* collections are contained is well got up, like other works of a similar character that have been brought out under the joint co-operation of the authorities of the National Museum of Denmark, and of the Carlsberg Institute. The latter of these bodies has liberally advanced the funds necessary for meeting the expenses of publication, in anticipation of the grant of 10,000 kroner to be voted for the purpose in the next year's Parliamentary Budget.

The work has been carefully edited by Herr Lütken, who contributes the monograph on the fishes, and to him foreign readers are indebted for a French *résumé* of the report on the vegetation of Nova Zembla, and for a general summary of the fauna of the Sea of Kara in the same tongue. Besides his very complete botanical reports, Herr Holm contributes a short prefatory account of the cruise, which, if it unfortunately failed in adding to our geographical knowledge of the Arctic regions, has at any rate supplied naturalists with much valuable material towards a closer acquaintance with the conditions and forms of vegetable and animal life in those high latitudes.

EXERCISES IN QUANTITATIVE CHEMICAL ANALYSIS.

Exercises in Quantitative Chemical Analysis; and a Short Treatise on Gas Analysis. W. Dittmar, LL.D. (Glasgow: William Hodge and Co., 1887.)

IT has probably been the case with all books on practical chemistry, and especially quantitative analysis, that in the first instance a rough plan or outline of the work was used by the teacher in his laboratory, there to undergo a process of extension and development. In some cases this development has gone on until we have such classical compilations of tried analytical processes as Fresenius's quantitative or Crookes's special methods. This seems to be a natural plan. Try your plan on your own students, and, if there a success, publish for the possible benefit of a wider circle. There is only this difficulty,

that, outside certain fundamental operations and stages in teaching, teachers and schools differ considerably in detail, and it is precisely on this detail, or order of importance in some cases, of work that a teacher prides himself —or thinks he has the right plan—as being able to turn out the most satisfactory students or to save their time.

The author of this book in his preface tells us that a preliminary edition was issued a little more than a year ago for his own students, and that the work had been even before then in use as a typographed book for some time. He likewise makes some remarks about the drilling of students in the beginning of their quantitative exercises with which we fully agree. Our experience is that a student requires standing over during the first four or five quantitative exercises. If the author's production shortens that ever so little, it will be a service to teacher and student alike. As to the interpolation of a preparation, the importance of this has scarcely been recognized by teachers. There is no doubt that a judicious selection of preparations, the end product of which is to be analyzed, is one of the best methods of preparing young students for practical analytical work.

After the exercises in weighing and measuring and determination of specific gravities of solutions, the book proceeds to a series of exercises in analytical methods. In these methods lies at once the strength and weakness of the book. We have a considerable number of methods for the analysis of things—salts, &c.—of technical importance, the performance of which would leave a student in a strong position as regards practical knowledge; but it is very questionable indeed if the average student could work through the majority of these, in the absence of the instructor, from what is given in the shape of directions. The exercises under separation are very well selected. They include a number of ores and alloys, silicates, &c. In the process of separation of lead and antimony by chlorine (p. 137) the author might have improved on the use of manganese by using permanganate, the evolution of chlorine is more regular.

Then follows combustion analysis for C, H, and N, and gas analysis. The latter forms the largest and best section of the book. It is mostly taken from, and is after the style of, Bunsen's gasometry. Other methods or modifications are also discussed as far as is requisite in a book of this nature. We have, finally, a number of "promiscuous exercises" in applied analysis: sea-water —mostly after the author's report on the composition of ocean water—milk, butter, and other substances.

On the whole, the book is a careful compilation and arrangement of work for students, bearing unmistakable evidence of the author by the references to his work and methods. We take leave to object to "Knallgas" as not being very generally understood by English students. It is not much shorter than electrolytic gas, and although the employment of it is explained it serves no very useful end. But this and one or two other details are not great objections, and do not detract from the utility of the book, which attempts perhaps too much, but may be fairly commended to those students of chemistry intending to become analysts, especially of technical products.

W. R. H.

THE STUDY OF LOGIC.

A Short Introduction to the Study of Logic. By Laurence Johnstone. (London: Longmans, Green, and Co., 1887.)

THERE is naturally some interest attaching to a book on logic which bears the *imprimatur* of Cardinal Manning, and of which a responsible member of the Society of Jesus can say *nihil obstat.* The Jesuits have long been famous teachers, and it is possible that those who find elementary logic an unsatisfactory teaching-subject may glean some useful hints from this little volume.

From a point of view outside the Roman Church, the perennial difficulty in the study of logic consists in the fact that no firm line can be drawn between the most elementary logical doctrines and the highest possible flights of philosophical reflection. As logic is taught by and for free-thinkers, both student and teacher are in a constant state of climbing ladders only to kick them down. At all stages a higher and a lower logic are at variance, or rather the higher logic consists in nothing else than a criticism of the lower. Distinctions that have been our mainstay become mere obstacles: our later views are mostly not additions to the earlier ones, but subversions of them. Hence there is little beyond the bare history of the subject, and a few of the less important technicalities, that can be taught with any authority.

In Mr. Johnstone's book we find throughout a wholly different attitude taken. With quiet simplicity, questions over which modern philosophy has spent much heat and labour are boldly prevented from arising. Thus a student may read, on page 10, under the heading "Action of the Intellect," that "the mind is a *tabula rasa* before it receives any impressions from without. It receives impressions, or the matter for ideas, through the senses, upon which the impression is made. By means of the 'sensus intimus' man becomes conscious of these impressions, of which the imagination then forms a picture, or phantasm." And then "from the picture on the imagination the intellect draws that element which is akin to itself, that is the immaterial incorporeal element, throws it into its mould—so to say—and the result is the 'species intelligibilis,' formed in the intellect itself, and representative of the exterior thing." What could be more final and satisfactory? It is not everyone who is free to make so short a piece of work of one of the largest of all philosophical questions. And so the student gets something that he can definitely carry away, and produce on paper when required.

Another noticeable feature is the revival, throughout the work, of many distinctions which have dropped out of sight in our modern text-books, or are at most referred to vaguely there with a passing smile at the "fruitless subtlety of the schoolmen." These can plainly be made to serve two purposes,—they provide abundance of material for the student to exercise his memory upon, and their effect as a whole must be to keep as separate as possible the process of using the machinery of logic, and that of seriously criticising our own beliefs. It is only from the free-thinker's point of view that any real desire can be felt to make logical criticism practically effective to the utmost. If we are anxious above all to

guard some piece of faith as such, then the more wordy our logic the better. And the delight in "naming our tools" may be carried to any length without fear of unpleasantness. It need commit us to no more than did Mr. Micawber's plan of docketing his unpaid bills. Here, however, it must be left an open question whether the modern practice of ignoring so many carefully-made divisions is an improvement or the reverse. Both views are at least respectable. In any case the elaborate details of the machinery by which our religious creeds are to be kept sacred contain much that ought to be of interest to all. What with *criteria per quod* and *secundum quod* (pp. 168, 191), with different "spheres" of truth (pp. 175, 202, 203), and different kinds of certainty (pp. 161-68), with truths which are "not intrinsically evident, but nevertheless extrinsically evident, or, rather, evidently credible" (p. 200), one may learn to admire heartily the care and cleverness employed so freely in mediæval times by those who felt the need of warding off awkward questions. It is certainly no light problem, how logic may be taught without encouraging the dangerous practice of doubting what we are told.

There are other signs of hard work in this book, besides the patience with which the author has studied the scholastic doctrines. For teaching purposes there is nothing so useful as examples, and here the examples given are numerous, mostly new, and sure to be helpful to the learner. Only those who have tried know the real difficulty of clearly illustrating statements so general as those of logic without some appearance of triviality. In this respect also Mr. Johnstone has succeeded unusually well.

ALFRED SIDGWICK.

OUR BOOK SHELF.

Light and Heat. By the Rev. F. W. Aveling, M.A., B.Sc. (London: Relfe Bros., 1887.)

THIS is an elementary text-book intended to cover the syllabus of Light and Heat for the London Matriculation Examination. Being written more in the form of notes than as an ordinary book, it will be of considerable service for examination-purposes. Many of the definitions, however, are far from concise, and many phenomena which admit of easy explanation are left unexplained. On p. 98 we are told that the specific heats of gases are inversely proportional to the square roots of their densities, whereas they are in inverse proportion to their densities; had a simple explanation of this relation been given, the mistake would not have occurred. The important subject of thermo-dynamics is disposed of in four pages at the end of the book: this is not as it ought to be, seeing that the relation between heat and work often enters into previous discussions, and is, moreover, the basis of the modern theory of heat.

The sketches are of a rough-and-ready kind, such as a student would be expected to make in an examination, and, as such, give many useful hints. The coloured plate of spectra, however, is as useless as the majority of similar ones, as practically no explanation of the meaning of a spectrum is given; dark lines are shown in the spectrum of potassium, but these are no doubt due to a mistake of the lithographer. Such exhibitions as these, which are far too common, show a want of respect for the labours of those who have done so much to further our knowledge of spectrum analysis.

A large number of good numerical problems, with answers, are distributed throughout the text, and several typical ones are fully worked out.

A. F.

Animals from the Life. By H. Leutemann. Edited by Arabella B. Buckley. (London: Stanford, 1887.)

THIS work, which forms a charming introduction to the study of zoology, is just the thing for young children who have a turn for the subject, and at the present time, since presents are being made on all sides, would make a very useful and enjoyable gift. From it they will be able to become acquainted with the various forms of living creatures without having to make a laborious study of natural history, which few care to do. A great amount of knowledge can be gained by merely looking at the illustrations, which are got up in a very intelligent and accurate style; they are 255 in number, and well coloured, and represent animals, including birds, insects, fish, &c., as they are found in their natural state.

The accounts of the various forms and habits of the different animals (each plate having about a page and a half of letterpress with it), are written so very clearly and in such a natural way that anyone who peruses this book will find plenty that will be extremely interesting.

In adapting the original text to the wants of English children, Miss Buckley has had to alter it in many places, English examples and references being substituted for German ones.

The Vegetable Lamb of Tartary. By Henry Lee. (London: Sampson Low, 1887.)

IN former times it was generally believed that there existed in the East a mysterious "plant-animal," variously called "the vegetable lamb of Tartary," "the Scythian lamb," and "the Barometz," or "Borametz." The usual explanation of this notion is that it originated from certain little lamb-like toy figures constructed by the Chinese from the rhizome and frond-stems of a tree-fern. Mr. Lee, however, holds that the idea came into Europe from Western Asia, and that it referred in the first instance to the cotton-pod. This theory he works out thoroughly in the present little work, and in the course of his argument he has brought together many curious and interesting facts, the significance of which is made more plain by a number of good illustrations. In a separate chapter Mr. Lee treats of the history of cotton, its uses by ancient races in Asia, Africa, and America, and its gradual introduction among the nations of Europe.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

The Royal Horticultural Society.

THE affairs of the Royal Horticultural Society alluded to in the last issue of NATURE (p. 145) have lately obtruded themselves upon public attention, but it is probable that some readers of NATURE may consider that they have little concern with such a body. They may look on horticulture in the light of a pleasant pastime, or of a more or less profitable commercial enterprise, they may regard flower-shows as a means for the display of fashionably-dressed ladies, or they may look on the Royal Horticultural Society as an association for the production and distribution of medals and certificates of more commercial than scientific importance. But there are other considerations beyond these, and whilst naturalists may be indifferent to much of the past history and much of the present work of the Society, to the internal dissensions and to the action of the landlord Commissioners towards their unfortunate tenants, the scientific work of the

Society may well excite their sympathy. A moment's consideration will show that the progress of horticulture is largely based on the correct application of scientific principles. What is not so familar to most people is the extent of the obligation under which science generally lies to horticulture. Should any reader require an illustration of this, let him turn to the "Origin of Species," and specially to the "Variation of Animals and Plants under Domestication." There is scarcely a page in the chapters of those volumes relating to plants that does not abound in references to the practices and the discoveries of horticulturists. Fertilization, cross-breeding, hybridization, selection, grafting, the limits and nature of variation, are only a few of the subjects on which horticulture furnishes the largest and in many respects the most trustworthy body of evidence yet available. That these subjects are studied, and that the experiments are made, not so much from a scientific as from a utilitarian point of view, is surely no matter of reproach. On the contrary, it is the business of horticulturists to act as they do, but without the aid of a Society much of the experience gained would be lost to science. All this might be admitted as a general principle, but yet its concrete application to the Royal Horticultural Society might be from various causes inappropriate. The Society in question has, however, distinct and undoubted claims to recognition for the good work it has done in science for a long period of years. The services it has rendered to science by its collectors, and the still greater value of its work in all departments of practical horticulture, should have secured for it more sympathetic and respectful treatment from its landlords. Among Societies deserving of national support and encouragement on the ground of public utility, there are few, indeed, that have greater claims than this. For years it has unfortunately been hampered by the necessity of providing amusement for a body of Fellows and visitors who cared nothing whatever for horticulture in its higher aims. Now there is a chance of the Society bursting its bonds and confining itself to its proper work —the promotion of scientific and practical horticulture. The plan of catering for fashionable idlers has proved disastrous. While horticulture proper was starved, and thousands upon thousands of pounds were utterly wasted, the landlords retain the whole of the property on which their tenants expended so much, and the Society has to seek a new home. In spite of all this, however, a valiant attempt has been made throughout long years of depression to maintain the scientific traditions of the Society. There has always been a small body of Fellows who have been mindful of the obligation which Thomas Andrew Knight, so long the President of the Society, imposed upon his successors. Lindley for forty years maintained the scientific interests of horticulture in the Society, and he was assisted by Royle, by Bentham, and many others. Twenty years ago, or more, a Scientific Committee was appointed, and this body, recruited by new accessions each year, still continues its labours. Under its guidance experiments have been performed in the Society's Experimental Garden at Chiswick; under its sanction have been published numerous Reports of very great scientific interest and importance; and much more might and could have been done but for the lack of means, or rather their diversion for more questionable purposes. The Committee in question consists of some twenty or thirty naturalists of all denominations—botanists, chemists, geologists, entomologists—associated with amateur and professional gardeners interested in science. To this body are referred for discussion and investigation the most varied objects of natural history and vegetable pathology; before this body and its sister committees are brought all new introductions, whether of natural origin, or produced by the skill of the gardener, and which have any scientific interest. Sir Joseph Hooker is the Chairman of this Committee, the Rev. M. J. Berkeley was for many years its Secretary, and a large number of the most eminent biologists, chemists, and geologists have been or still are among its members, giving their services without fee or reward, simply in the interests of scientific horticulture. On these grounds, therefore, the sympathy and co-operation of those interested in science may be claimed on behalf of the Royal Horticultural Society. A new programme has been decided on in principle, a new home must be provided at once, for the purpose of the Society's meetings and for housing the Lindley Library. This library, it may be added, is held in trust for the benefit of the Society, and is from time to time enriched by donations and by purchase, so far as the very meagre income of the Trustees permits. The donations would be much more numerous were it generally known that the library, though primarily intended for the Fellows, yet is under certain restrictions available to outsiders, so that, though housed in the Society's rooms, it cannot be sold or made away with in any financial catastrophe which might overtake the Society. Such a fate, however, seems to be averted at present; the Society's debt is not large, and some members of the Council, or other friends, have made a good beginning by inaugurating a fund, to be used for the housing of the Society, so that ere long we may hope to see the old Society established on a more secure basis, and more potent than ever to advance those interests of science committed to its special keeping.

MAXWELL T. MASTERS.

Classification of Clouds.

As one who has been engaged for nearly forty years in working up the materials for a monograph on clouds, I suppose I deserve the name of a "specialist in clouds" as much as any one. Yet I decline, for reasons which I will hereafter state in an appendix to my volume, to be altogether bound by the outlines of classification which my friends Prof. Hildebrandsson and the Hon. Ralph Abercromby appear to lay down (NATURE, December 8, p. 129 *et seq.*), although they adopt several of the names which come from my mint. I fully adopt the opinion implicitly held by Mr. Abercromby, and stated by my friend Captain Barker (*ibid.*)—from whose classification, however, I differ in one important point—that all ordinarily careful observers will readily comprehend the broad and simple distinctions expressed in any fairly good classification. Nevertheless, I believe that the apparently slow progress of this branch of research, and the tediousness of the work thrown upon the classifier, are matters on which we should congratulate ourselves, since every year adds something to our knowledge of those physical and structural processes which form the basis of all true classification; and I trust that some years may pass before an International Congress may attempt finally to set its seal upon any nomenclature or classification of clouds.

W. CLEMENT LEY.

Effect of Snow on the Polarization of the Sky.

THE polarization of the sky has been shown experimentally by Tyndall and theoretically by Lord Rayleigh to be due to fine particles suspended in the atmosphere. According to both, the sunlight scattered at right angles to its original direction by very small particles is completely polarized in a plane through the sun. In observation, however, we find the light from a region of the sky distant 90° from the sun is only partially polarized. This is due to that portion of the atmosphere being illuminated not merely by the sun, but also by the rest of the sky and the surface of the earth, and partly also no doubt to some of the particles not being sufficiently small compared with a wave-length. From these considerations we may expect that a fall of snow would cause a considerable diminution of the polarization. This expectation has been fulfilled in some recent observations of mine here at 6000 feet above sea-level. My polarimeter consists essentially of two piles of glass plates to depolarize the sky light; and a crystal and Nicol prism to test the depolarization. Owing to the strength of the polarization at this altitude, I find it necessary to use two piles of glass plates separated by two or three inches. This arrangement diminishes the number of double internal reflections, and so is a much more powerful polarizer or depolarizer than the same number of plates combined into one pile. As I have not seen this important practical consideration noticed before, I may point out that, in addition to the light refracted directly through the pile, there are a number of portions twice reflected. One of these for instance is reflected first at the second surface of the last plate, and secondly at the first surface of the last plate. The number of such twice-reflected portions for n plates is $n(2n - 1)$. When, as in my instrument, the fixed pile is much inclined, no light can reach the edge after being reflected first by one pile and then by the other. If the two piles were combined into one, I should have 120 portions twice reflected; as it is, I have only 60. This increases the polarizing power of the instrument by at least one-third.

The crystal is a thick plate of Iceland spar cut so that the light passes along the optic axis. The fixed pile of three plates has its normal inclined at 47° to the axis of the crystal. The movable pile of five plates has an index attached, which gives the inclination of its normal to the axis of the crystal. This inclination is the reading of the polarimeter.

St. Moritz lies on the northern slope of a valley running from south-west to north-east. At the beginning of the observations the opposite slope was buried in snow, but the northern slope both above and below the point of observation was almost free from snow. Thus the most brightly illuminated part of the ground surface was of a dull brown or gray colour. Under these circumstances, the reading was about 50° in the middle of the day, being a little higher earlier and later, viz. about 52° at 10 a.m. (date October 21 and 22). These readings, as well as those mentioned below, refer to the highest point of the sky, which is distant 90° from the sun, and were taken when the whole sky was free from cloud. On October 26, after a five-inch fall of snow, the reading was 41° at 10.15 a.m.

By October 29 most of the fresh snow had gone, and I found at 11.40 a.m. the reading as high as 48°. After this we had several feet of snow, and at 12.50 p.m. on November 13, the reading was again 41°. Each of these readings is the mean of four, and I find two readings of the same thing seldom differ more than 2°. Hitherto I have not been able properly to evaluate the readings of my instrument in absolute measure, though I hope to do so later. But to gain an approximate idea of their meaning, I have calculated the polarizing power of the two piles on the assumptions—first that Fresnel's laws of the reflection of polarized light are accurate, and secondly that the index of refraction of my plates is 1·52. We may consider the light from the sky as consisting of two parts completely polarized, one in the plane of the sun, and the other perpendicular thereto. The ratio of these parts is ·376 for the reading 40°, and ·271 for the reading 50°. Again we may divide the light into a part unpolarized and a part completely polarized in the plane of the sun. The ratio of these parts is ·546 for 40° and ·428 for 50°. So it seems fair to conclude that the light reflected from the fresh snow was sufficient to increase the unpolarized part of the sky light by more than a quarter.

JAMES C. MCCONNEL.

St. Moritz, Switzerland, December 10.

The Ffynnon Beuno and Cae Gwyn Caves.

I WILL answer Dr. Hicks's question in as few words as possible. Nothing is to be gained by terming me a "highly prejudiced" observer, or by saying my views are of "no consequence" and "not worth anything." Your readers can form their own conclusions on these points. I am not "highly prejudiced" against, neither have I any "bias against," the existence of pre-Glacial man or of his "migrations"; on the contrary, I favour these subjects.

I *did* see the section of drift exposed at the Cae Gwyn Cave, and I can hardly describe it (from my own point of view) without giving offence. My view is this: the section showed nothing but rain-wash derived from the closely-adjoining non-Glacial drift. The section showed a re-made deposit, horizontally stratified, and with stones resting on their flat sides. No doubt there were Glacial stones in the rain-wash, derived from the ever-shifting post-Glacial marine drift close by; the latter being merely a re-laid Glacial drift. Stones with Glacial scratches may be found in the lower gravels of the Thames.

To me, the caves and their surroundings are in the highest degree suspicious, and in size insignificant, and not comparable with large and typical caves. They are small and painfully narrow tortuous passages only, on a hill-side, and *close to the surface*. The lower cave is furnished with a very large hole, opening up to the surface just above; and the upper cave had at one time a similar opening. The post-Glacial drift above is always on the move, and every shower of rain brings it down with its derived stones.

Since writing to NATURE, in November 3, I have referred to some of the papers published on these caves. I turned first to the list of mammalian remains, only however to find that the animals (like the implements) are entirely *characteristic* of the most recent post-Glacial deposits. Even near London we get in gravels of no great comparative antiquity the bones of *Elephas antiquus*, but in the caves merely *E. primigenius* is found. As regards antiquity, the animals no doubt overlap at both ends of the scale, but their meaning, as found in these caves, points in one direction only, and that is to the most recent and not to the most remote of Palæolithic times. None of the cave mammals are *characteristic* of pre-Glacial deposits.

It would seem that Dr. Hicks does not realize the nature of Dr. John Evans's criticism. La Madelaine is the newest of caves, and represents the most recent of Palæolithic times: it is a kind of connecting link between Palæolithic and Neolithic times. Therefore, if Dr. Evans's criticism is taken with mine, the two *clearly prove* that there *is* a distinct chronological value in the classification, not that there is "no chronological value" as concluded by Dr. Hicks. Dr. Hicks also appears not to realize the fact that river-drift and cave implements do not only differ in roughness and abrasion but in style. The cave men used different implements from the river-drift men, they were changing from savagery to barbarism. If Dr. Hicks produces implements made by pre-Glacial men, he must show us something obviously older than the oldest river-drift tools, not fall back upon refined tools which are, to re-quote Dr. Evans, "precisely like many from the French caves of the reindeer period, such for instance as La Madelaine." If Dr. Hicks abandons his scraper, he is still in no better position, for his finely re-trimmed knife and the implement in the British Museum are identical in age and character with it. So are the flakes: the one with long narrow facets is characteristic of the latest, not of the earliest work. So is the pointed and drilled bone. No drilled bones have been found in moderately old river-gravels, and what is more, no instrument suitable for boring a small hole through bone has ever been found in such a gravel. Drilled bones and small flint drills belong to the very latest of Palæolithic times. In the remains of my own collection of Palæolithic implements I have here over a thousand examples of the major class, and an equal number of minor forms illustrative of the development of knife and scraper forms, but they give no support whatever to Dr. Hicks's conclusions; they all, in fact, point in a diametrically different direction. I am acquainted with Prof. Prestwich's views, and I believe I was the first person to find implements in the highest terraces of the Thames Valley; but I do not see that Prof. Prestwich's conclusions have any direct bearing on the Ffynnon Beuno and Cae Gwyn caves.

I do not suppose that any opinion of mine will influence Dr. Hicks, and I have no wish to influence him or any other observer. I merely wish to put on record the fact that, after many years' experience amongst drifts, and implements, and fossil bones, my conclusions are entirely opposed to Dr. Hicks's.

Dunstable. WORTHINGTON G. SMITH.

P.S.—Since the above has been in type, I have seen the report in last week's NATURE (p. 166), but I prefer to let my letter stand just as written before the report was seen by me. Prof. Hughes has cut away the geological and palæontological supports; I shall be content to resist the idea of the pre Glacial age of these caves on purely archæological grounds.—W. G. S.

The Planet Mercury.

THE planet observed on the mornings of December 7 and 9 by your correspondent "G. F. P." (NATURE, December 15, p. 151), was probably not Mercury but Jupiter, as these bodies were near together at the time, and the latter was by far the brightest and most conspicuous. The circumstances, described by "G. F. P.," under which the object was noticed render it certain that it could not have been Mercury, for the latter was decidedly small, and might have been easily overlooked on the several mornings I saw it early in the present month. Jupiter, on the other hand, was very bright and plain, and might easily attract attention in the way stated by your correspondent. On the 9th instant the two planets were about 3° apart, Jupiter being situated to the west of Mercury.

Had "G. F. P." really observed the latter planet, he would have instantly remarked its half-moon phase in his $3\frac{3}{4}$-inch telescope, and must have mentioned Jupiter, as well as Venus, as visible at the same time.

There is no difficulty in observing Mercury with the naked eye if the planet is carefully looked for in the proper spot, at the times of his eastern elongations in the first half of the year and at the western elongations in the last half. I have seen the planet on certainly more than fifty occasions. In May 1876 I noticed Mercury on thirteen different evenings. Sometimes the planet is quite conspicuous in the twilight as a naked-eye object.

W. F. DENNING.

Bristol, December 16.

Meteor of November 15.

IN NATURE of December 1 (p. 105) Mr. B. Truscott writes of a wonderfully fine meteor seen at Falmouth on the night of Tuesday, the 15th ult, and asks in effect if it was seen by other

eyes than his: so perhaps it may be permitted to be said that it was seen in the parish of Llanefydd, Denbighshire, by a correspondent of mine, who writes:—"On Tuesday night, November 15, while returning homewards on foot, happening to look eastwards I saw a long train of brilliant light suddenly flash out of the sky. At first I thought it was lightning. But instead of vanishing it descended with great rapidity, the light increasing in brilliancy as it neared the earth. The night was rather dark, although the sky was thickly studded with stars, but in a few seconds so intensely brilliant had the light become that a pin might have been picked up from the road with the greatest ease. While I was looking, the object that accompanied the flash burst, and displayed a magnificent mauve and red fringe of light. I say fringe, as it would be impossible for me to describe otherwise the shape, for it appeared to me to project shafts of light, some long and some short, like what would be the rays of a great star. There was in the direction in which I was looking a thick wood, and the effect on the trees of the silvery light I first noticed was richly beautiful. But the effect of the mauve and red light was magnificently grand, and to me in no little degree awful. The whole wood was enveloped in a red lurid glare, which lasted as near as I can calculate some six or eight seconds. The effect altogether was like a brilliant transformation scene, and the meteor having passed away, the darkness of the night seemed to be in the last degree intense."

J. Lloyd Bozward.

A Correction.

In the footnote, p. 152, second column, there is an unfortunate transposition for which myself more than the printers are to blame, which it is important to correct.

After the words "by Aristotle, Probl. 1 E 3 and Metaph. A 5" occur the words "which he attributes to Pythagoras . . . . on the nature of the Beast."

These words should have come at the end of the subsequent paragraph where I say that "Muhamad-al-Sharastani assigns *reasons* for regarding all the numbers up to 10 inclusive as perfect numbers."

It is these *reasons* which I speak of as being by him attributed to Pythagoras, &c.

I may take this opportunity of giving, as another example of the use of the New Nomenclature, the well-known *extended* Theorem of Fermat, which may be expressed by saying:

"Every number must divide the Fermatian of which the index is its *totient*, and the base any one of its *totitives*."

Athenæum Club, December 15. J. J. Sylvester.

ISOLATION OF FLUORINE.

ONE of the most difficult problems of modern chemistry has at last been satisfactorily solved. After three years of incessant labour, occasionally interrupted by temporary feelings akin to despair, M. Henri Moissan has at length isolated in considerable quantities that most baffling of elements—fluorine, and has been enabled to determine its principal properties. The experiments themselves are among the most interesting ever performed, and their details, as described by M. Moissan in the December number of the *Annales de Chimie et de Physique*, form the most fascinating reading. They must of necessity have been extremely costly, for by far the greater portion of the apparatus employed was constructed of platinum, and it is not often that one hears of a platinum tube 80 centimetres long and of 1½ centimetre diameter being destroyed in each experiment, as happened in the earlier stages of these researches.

The isolation of fluorine has formed a worthy object of the attention of chemists ever since the first remarkable experiments of Sir Humphry Davy, who was rendered dangerously ill by being exposed to the corrosive fumes of hydrofluoric acid. Although Davy was not successful in obtaining free fluorine, yet he brought clearly to light the nature of hydrofluoric acid, and proved it to consist of hydrogen combined with an unknown but extremely active element—fluorine. The history of all the attempts which have since been made to effect the preparation of free fluorine might occupy a volume, and it will therefore only be necessary to refer to the later work of our countryman, Gore, who, in 1869, published his researches upon the electrolysis of hydrofluoric acid, and of certain fluorides, and left our knowledge of the acid itself in a most complete state. M. Moissan, working in the laboratory of M. Debray, now steps in and achieves the result so ardently sought after during the last eighty years—another example of the irresistible power of human perseverance.

In the light of the experience gained by former experimenters, it appeared that the action of a powerful electric current upon the compounds of fluorine with the non-metallic elements, such as hydrogen, phosphorus, and arsenic, would be most likely to yield the desired result; knowing also that fluorine must be an extremely energetic substance, it was absolutely essential to work at very low temperatures. Hence M. Moissan's first attack was made upon the fluorides of phosphorus and arsenic, but finding these to be practically impregnable, he diverted his attack, guided by certain indications afforded during his first attempt, upon hydrofluoric acid itself. Finding, however, that pure hydrofluoric acid is an exceptionally bad conductor of electricity, as has been stated by other workers—that even a current from fifty Bunsen cells would not pass through the liquid—he eventually, after several essays, succeeded in converting it into a conductor by dissolving in it a quantity of the double fluoride of potassium and hydrogen. On passing the current from twenty Bunsen cells through the now conducting medium, hydrogen immediately commenced to be evolved at the negative terminal, while fluorine was with similar rapidity evolved at the positive pole, and exhibited its tremendous activity upon everything that came near it: burning up hard crystalline silicon like tinder, setting fire to organic matter, and forming fluorides with incandescence with many other elements.

Having thus indicated the general course of these researches, it will no doubt be interesting to follow M. Moissan during the carrying out of his principal experiments.

The first series consisted in examining the action of electric induction sparks upon the gaseous fluorides of silicon, phosphorus, and arsenic. The gases were introduced into glass eudiometer tubes standing over mercury, and the spark was passed between two platinum wires connected with an induction-coil actuated by a few Grenet or Bunsen cells. On introducing dry silicon tetrafluoride, SiF_4, and passing sparks for an hour, no decomposition was effected, the result being discouragingly *nil.* Dry phosphorus trifluoride, PF_3, however, behaved quite differently, phosphorus being deposited upon the inner wall of the tube; but the fluorine liberated at once combined with the residual trifluoride to form the more stable pentafluoride, PF_5. Some time ago this pentafluoride of phosphorus was prepared by Prof. Thorpe, who also submitted it to the action of the induction-spark, unfortunately without effecting any decomposition. Precisely the same result has been arrived at by M. Moissan, using a 0·04m. spark; but on obtaining sparks 0·2m. long, a rapid etching of the walls of the glass tube occurred, and the meniscus of mercury entirely lost its brilliancy. After an hour's duration the experiment was concluded, and the apparatus allowed to cool, when it was noticed that the volume had diminished; moreover, the gas was found to have changed its properties, yielding a precipitate of silica in contact with water, while the residual gas consisted of the trifluoride of phosphorus. Hence $PF_5 = PF_3 + F_2$, which latter forms, with the glass, silicon tetrafluoride, and, with the mercury, fluoride of mercury. So here again the experiment was disappointing, and although fluorine was for the moment liberated, this method was certainly not suitable for the preparation of free fluorine.

Fluoride of arsenic, AsF_3, the next fluoride experimented upon, was first prepared by M. Dumas, who was severely injured in the experiment. It is a liquid which boils at 63° C., and may be easily maintained in a gaseous condition, by use of a steam jacket, and submitted to the action of the spark. It is, however, a most disagreeable substance to work with, as it produces most terrible sores when by any mischance it comes in contact with the operator's skin. On passing sparks through it for an hour, as in case of the pentafluoride of phosphorus, the platinum wires became covered with a black incrustation of arsenic, while the walls of the tube were strongly corroded. On testing the gas, it was found to contain a large quantity of silicon tetrafluoride mixed with a smaller quantity of free fluorine, which displaced sufficient iodine from a solution of potassium iodide to give a good coloration to several cubic centimetres of chloroform. Clearly, progress was being slowly made, though still far from the isolation of fluorine.

And now a remarkable experiment of a new type was performed. It had been noticed that, on passing an electric current through a platinum wire in an atmosphere of phosphorus trifluoride, the platinum fused owing to the formation of a fusible phosphide of platinum; at the same time the glass of the containing vessel was etched and the mercury attacked. So the experiment was repeated on a grander scale. A quantity of spongy platinum, previously washed with hydrofluoric acid and calcined, was placed in a platinum tube 80 cm. long, and of 1·5 cm. diameter; that portion of the platinum tube which required to be heated was incased in a second outer tube of glazed porcelain, so that between the two a current of nitrogen could be kept circulating, and so prevent access of furnace gases. The tube was then heated in a furnace, and pure hydrogen passed through it for some time to remove all other gases; afterwards pure nitrogen was substituted, and finally phosphorus trifluoride. After passing a short time, the current of fluoride was suddenly stopped with a most singular result: a partial vacuum was caused, owing to absorption by the platinum.

When, however, the current of trifluoride was passed more rapidly, a small quantity of pentafluoride was formed; the fluorine liberated, when the absorption of phosphorus by the platinum occurred, having combined with the trifluoride just as in the spark experiment. But, on examining the gas which passed out of the tube under these conditions, it was found to liberate iodine from potassium iodide, attack mercury, and etch glass. In fact, it was proved that free fluorine was liberated, and mostly absorbed by the platinum, causing the diminution of pressure on stopping the current, but being more or less carried away when the current was more rapid. The fluophosphide of platinum formed was found to contain only 70 to 80 per cent. of platinum, and the formation of this substance was so rapidly effected that every experiment required a new tube. The action of pentafluoride of phosphorus upon platinum was next tried, and with still more encouraging results. On sweeping the tube, heated in a coke blast-furnace, with a rapid stream of the pentafluoride for some minutes, then moderating the rapidity, and five minutes later again increasing the speed, the issuing gas was found to blacken solid potassium iodide by liberating free iodine, inflame phosphorus, and attack crystalline silicon, glass, and mercury. It was, in fact, free fluorine drowned in excess of trifluoride of phosphorus. This was a decided advance, and the outlook was becoming considerably more hopeful.

The next experiments were made with liquid fluoride of arsenic, AsF_3, a quantity of which was placed in a platinum crucible, which served as the negative electrode. A platinum wire, dipping into the liquid in the crucible, and reaching to within 5 millimetres of the base, served as the positive electrode. The current from three Grenet cells was then passed through the liquid, causing a deposition of arsenic upon the interior surface of the crucible, but no gas could be perceived at the positive pole. However, on dipping the platinum wire into a solution of starch paste and potassium iodide, blue striæ were at once formed in the solution, showing the presence of a condensed gas sheath of fluorine around the platinum wire. Following up this indication, the current from twenty-five Bunsen cells arranged in series was next employed, and immediately the deposition of arsenic commenced upon the walls of the crucible, while bubbles of gas were evolved around the platinum wire. Unfortunately the action soon ceased, owing to the bad conductivity of the liquid and of the thick deposit of arsenic. The wire, however, was strongly attacked. So attempts were next made to increase the conductivity of the fluoride by the addition of metallic fluorides, and it was soon discovered that the best results were obtained by use of the double fluoride of hydrogen and potassium, HF . KF. It was probably this discovery which led to the grand success with which these efforts have been finally crowned, for, as has been previously mentioned, it was by the electrolysis of this double fluoride that M. Moissan eventually succeeded in preparing free fluorine.

Before leaving the experiments upon arsenic fluoride, it may be mentioned that it was eventually electrolyzed in a continuous manner by use of seventy to ninety Bunsen cells, the arsenic liberated remaining in suspension in the liquid, instead of adhering to the tube, but the bubbles were rapidly seen to diminish in size in passing through the liquid, and scarcely a trace of gas escaped; instead of permitting its isolation, the fluorine preferred to form a new fluoride, the pentafluoride of arsenic, thus once more baffling the ingenious experimenter.

But success was not now far away. The wonderful manner in which the double fluoride of potassium and hydrogen increased the conductivity of arsenic fluoride determined M. Moissan in employing it for the same purpose in an attempt to electrolyze pure anhydrous hydrofluoric acid. Faraday long ago showed that the electric current will not pass through the anhydrous acid, and Gore more recently came to the same conclusion. The current from fifty Bunsen cells was found by M. Moissan to be absolutely powerless to penetrate the acid used in these later experiments. But, on dissolving a few fragments of the double fluoride HF . KF in the acid, the current at once passed freely, and the experiment thus became possible. The apparatus used in the first attempts with this mixture consisted of a platinum U-tube, of which each branch was closed by a paraffined cork, through which the rods of platinum forming the poles were passed. Upon each branch, just above the level of the liquid and beneath the cork, was soldered a little platinum delivery-tube to lead off the gases evolved. As hydrofluoric acid boils at 19°·4 C., the apparatus was immersed in a bath of methyl chloride, which boils at −23°, but which could be reduced in temperature to −50° by driving through it a current of dry air. Hence the electrolysis could be conducted without fear of the gaseous products being drowned in excess of vapour of hydrofluoric acid, and the activity of the liberated fluorine was at the same time moderated. On passing the current, a gas was at once produced at each electrode, a regular evolution of hydrogen at the negative pole, and a continuous disengagement of gas at the positive pole. But still affairs were not satisfactory: crystalline silicon did not take fire when held in the gas coming off from the positive pole; so the apparatus was taken to pieces an hour later, in order, if possible, to find a clue to the source of failure. The paraffined cork at the negative branch was intact, but, behold the mischief, the other was carbonized to the depth of a centimetre; so the liberated fluorine had extracted hydrogen out of the cork, and passed on as hydrofluoric acid. The positive platinum rod was also much corroded. Closely-fitting stoppers of fluor-spar were next tried, coated with melted

gutta-percha, but the latter again soon melted on passing the current, and was put *hors de service*. Gum-lac and many other substances were tried, but all to no purpose, and much precious time was lost. Finally, however, the difficulty was overcome by using stoppers of fluor-spar, carefully inserted in hollow cylinders of platinum carrying fine screw-threads upon their outer surfaces, which engaged with corresponding threads upon the interior surfaces of the two branches of the U-tube. The platinum rods passed through the axis of each cylinder of fluor-spar: the rods themselves were of square section, of 2 millimetres side and 12 centimetres long, and passed to 3 millimetres from the base of the U-tube; they were made of irido-platinum, containing 10 per cent. iridium, which is less attackable than pure platinum. The U-tube simply consisted of a platinum tube, bent twice at right angles, 1·5 centimetre diameter and 9·5 centimetres high, and was fitted with side tubes and immersed in methyl chloride as before.

The pure anhydrous hydrofluoric acid, which was the next necessity, was prepared in the following manner. A known volume of commercial acid was treated with sufficient potassium carbonate to neutralize about a quarter of it, and then distilled in a leaden retort over an oil bath at 120°. At this temperature the fluosilicate of potassium, formed from the hydrofluosilicic acid, contained as impurity in the commercial acid, was not decomposed, and the distillate was therefore free from silica. This distillate was then divided into two parts, and one half, saturated with pure potassium carbonate, forming neutral potassium fluoride, was then added to the other half, and transformed into HF . KF. The double fluoride was then dried at 100°, and afterwards kept for some days in the vacuous receiver of an air-pump, containing also strong sulphuric acid and a few sticks of fused potash. When absolutely dry it fell to powder, and was then ready for the preparation of hydrofluoric acid, which was always freshly prepared immediately before each experiment. The dry fluoride was in each case introduced into a recently ignited platinum retort, and maintained at a moderate heat for some time so as to commence the decomposition slowly; the first portions of distillate were rejected, as they would contain the last traces of water. The platinum receiver was then adapted and surrounded by ice and salt; on heating the retort more strongly, pure hydrofluoric acid condensed in the receiver as a limpid liquid boiling at 19°·4, very hygroscopic and fuming in the air.

While the preparation of the acid was in progress, the U-tube and electrodes were drying at 120°. From 6 to 7 grammes of the dry double fluoride were now introduced into the apparatus, the stoppers were screwed in and covered with gum lac. The whole was then fixed in the methyl chloride bath, and, until the introduction of the acid, the delivery-tubes were connected with desiccators containing fused potash. A constant supply of methyl chloride at − 23° was maintained in the outer cylinder, as a slight rise of temperature allowed of the volatilization of some of the acid. About 15 to 16 grammes of the anhydrous hydrofluoric acid were then gently aspirated into the apparatus, and the current from twenty Bunsen cells allowed to pass, when immediately a regular evolution of gas occurred at each pole. At the negative pole pure hydrogen was evolved, which burnt with its characteristic flame, forming water. At the positive pole was liberated a colourless gas of penetrating and very disagreeable odour, somewhat resembling that of hypochlorous acid, and rapidly irritating the mucous membranes of the throat and eyes. It was no other than pure fluorine itself. All the trouble, all the expense, and all the disappointments were repaid. It must indeed have been a supreme moment for M. Moissan.

In order to study its action upon solids, they were placed in small glass tubes, and brought near to the orifice of the platinum delivery-tube at the positive side. The test was generally repeated, holding the solids in small platinum capsules.

Sulphur, brought thus near the orifice, at once melted and inflamed; selenium behaved in like manner; as did also tellurium, with incandescence, forming fumes and becoming coated with a solid fluoride.

Phosphorus at once took fire, forming tri-, penta-, and oxyfluorides. Powdered arsenic and antimony combined with incandescence, the former yielding drops of AsF_3.

A fragment of iodine placed in the gas combined with production of a pale blue flame; in an atmosphere of iodine vapour fluorine itself burnt with a similar flame. Vapour of bromine lost its colour and the combination was sometimes accompanied by detonation.

Cold crystalline silicon at once became incandescent, and burnt with great brilliancy, sometimes with scintillations. On closing the little tubes containing it with the thumb and opening under water, the silicon tetrafluoride formed was absorbed and decomposed with precipitation of silica. Any undecomposed silicon was found to have been fused.

Debray's adamantine boron also burnt in the gas, becoming incandescent and giving off fumes.

Fluorine has a most extreme affinity for hydrogen; they combine in the dark with explosion. In one of the experiments the electrolysis was allowed to continue several hours, so that eventually the small quantity of undecomposed acid remaining in the U-tube was insufficient to keep the two gases apart; the experimenters were consequently suddenly startled by a violent detonation. The hydrogen and fluorine had combined in the dark at the low temperature of − 23°. The same detonation was afterwards brought about on a smaller scale by reversing the current. On bringing the wide-mouthed delivery-tube of a hydrogen generator near the orifice, the detonation at once occurred, and the hydrogen inflamed.

Metals are all attacked with more or less energy by fluorine, forming fluorides. Cold sodium and potassium were at once rendered incandescent. Calcium, magnesium, and aluminium acted similarly, in a more modified manner, becoming incandescent when slightly warmed. Powdered iron and manganese, on gently warming, burnt with bright scintillations; lead was attacked in the cold, and tin at a slightly elevated temperature. Mercury, as suspected, entirely absorbed the gas, forming yellow protofluoride. Silver at a gentle heat became coated with a beautiful satin-like fluoride, soluble, unlike the chloride, in water. Gold and platinum at 300°-400° became coated with their respective fluorides, which were decomposed again at a red heat, with evolution of free fluorine.

Perhaps the strongest evidence of the intense chemical activity of fluorine is exhibited in its action upon cold potassium chloride: the chlorine was at once expelled, filling the air with its disagreeable odour, and was identified by the usual chemical tests. Chlorine was also expelled from its combination with carbon in carbon tetrachloride.

All organic compounds are violently attacked by fluorine: a piece of cork at once carbonized and inflamed; alcohol, ether, benzene, and turpentine took fire immediately in contact with it.

Glass, as might have been expected, is at once corroded by fluorine; some very delicate experiments were carried out with perfectly dried glass, with the same result.

Many other reactions, all interesting and all showing the immense energy with which the atoms of fluorine are endowed, were performed, but one especially ought to be noticed, viz. the action of fluorine upon water. It is a singular fact that, whenever oxygen is liberated in the cold, there is a great tendency to form ozone: hence when fluorine is attempted to be collected over water, the gas collected is not fluorine, but ozonized oxygen; water is decomposed by the fluorine forming hydrofluoric acid,

while the oxygen is set free, and a considerable quantity of it is converted into the more condensed form of ozone.

On taking the apparatus to pieces after each experiment, the hydrofluoric acid remaining was found to contain a small quantity of platinum fluoride in solution, and a black mud consisting of a mixture of iridium and platinum in suspension. The negative electrode was not attacked, but the platinum rod forming the positive pole was eaten away to a point, so that one rod only served for two experiments. The average delivery of gas was about 1·5 to 2 litres per hour.

With regard to the chemical processes involved in the electrolysis, it appears probable that potassium fluoride is first decomposed into fluorine, which is evolved at the positive pole, and potassium, which decomposes hydrofluoric acid, liberating its equivalent of hydrogen at the negative pole, and re-forming potassium fluoride, which may again be electrolyzed. Hence a small quantity of the double fluoride can serve for the decomposition of a comparatively large amount of hydrofluoric acid.

The double fluoride HF . KF is very soluble in hydrofluoric acid, forming a crystallizable compound, richer in hydrofluoric acid than HF . KF, and which gives off no acid vapour at the boiling-point of the anhydrous acid, 19°·4. It is this compound which one ought to seek to obtain for electrolysis, as it is very soluble in excess of acid, forming a liquid of good conductivity.

The double fluoride HF . KF itself was finally electrolyzed by M. Moissan. It fuses at 140° to a colourless liquid which is quite suitable for electrolysis. The experiment was performed, as before, in a platinum U-tube, and, on passing the current, fluorine was again liberated at the positive pole, and at once set fire to crystalline silicon; but the platinum was strongly attacked, so the experiment was stopped in order to save the tube. On plunging a couple of platinum wires connected with the battery into a quantity of the fused double fluoride contained in a platinum crucible, gas was evolved in abundance at each pole, and on bringing the wires in contact, even in the dark, detonation occurred, owing to the combination of the evolved hydrogen and fluorine. At the same time the platinum wire from which the fluorine was evolved was almost entirely eaten away.

In concluding these remarkable researches, which have happily terminated so successfully, M. Moissan discusses very fully the question of the identity of the gas liberated at the positive pole with the element fluorine; and there can be no doubt that he has completely proved this identity, at the same time showing that fluorine occupies the place of honour as the most intensely active chemical element with which we are at present acquainted, and that it assumes its rightful position, theoretically destined for it, at the head of the group of halogens.

A. E. TUTTON.

TIMBER, AND SOME OF ITS DISEASES.

I.

ON carefully examining the clean-cut end of a sawn log of timber, it is easy to convince ourselves of the existence of certain marks upon it, which have reference to its structure. These marks will vary in intensity and number according to the kind of tree, the age at which it is felled, and some other circumstances, which may be overlooked for the present; but in a given case it would be possible to observe some such marks as those indicated in Fig. 1. In the specimen chosen there is a nearly central spot, the pith, around which numerous concentric lines—the "annual rings"—run. Radiating from the pith towards the periphery are cracks, the number, and length, and breadth of which may vary according to the time the log has been exposed to the weather, and other circumstances; these cracks are due to the contraction of the wood as it "shrinks," and they coincide with medullary rays, as lines of weakness. Between these cracks are to be seen numerous very fine radiating lines indicating the course of the uninjured medullary rays, which again will vary in distinctness, &c., according to the species of timber.

FIG. 1.—A log of timber, showing radial cracks after lying exposed for some time. *a*, a large crack extending from pith to circumference; *b*, the cortex; *c*, medullary ray; *d*, cambium; *e*, annual ring; *f*, outer bark, proper. Reduced.

This log of wood, with its annual rings and medullary rays, is clothed by a sort of jacket, consisting of cork and softer tissues, and termed the cortex, or, more popularly, the "bark" (an unfortunate word, which has caused much trouble in its time). The largest of the cracks is seen to traverse the whole radius of the face of the wood from centre to circumference, and also to pass through the cortex, which gapes widely.

The remaining cracks, however, stop short at a line which marks on the one hand the inner face of the cortex, and on the other the outer face of the wood: this line also represents the cambium, a thin sheet of generative tissue which remains after giving rise to practically the whole of the wood (a very little in the centre excepted) and cortex visible in the woodcut. Since we are not concerned with the cortex and bark at present, it will be convenient to regard the log as "barked," and only deal with the wood or timber itself, in the condition to which the woodman reduces it after removing the cortex with certain implements.

If now we split such a log as Fig. 1 along the line of the big crack, neatly and smoothly, the well-known "grain" so often observed on planks of wood will come into view, and it will be noticed that the lines which mark the "grain" are continuations of the lines which mark

the annual rings, as shown in Fig. 2, which represents on a larger scale a segment such as could be cut from a log in the way described. It is clear from comparison of what has been said, and of the two figures, that the "annual rings" are simply the expression in cross-section of cylindrical sheets laid concentrically one over the other, the outermost one being that last formed. But on examining the medullary rays in such a piece of timber as that in Fig. 2, it will be noticed that they also are the expression of narrow radial vertical plates which run through the concentric sheets: the medullary rays are in fact arranged somewhat like the spokes of a paddle-wheel of an old steamer, only they differ in length, breadth, and depth, as seen by comparing the three faces of the figure. It is to be noticed that the medullary rays consist of a different kind of tissue from that which they traverse, a fact which can only be indicated in the figure by the depth of shading. It is also to be observed that the "annual rings" show differences in respect to their tissue, as marked by the darker shading near the boundary lines on the outer margin of each ring. In order to understand these points better, it is necessary to look at a piece of our block of timber somewhat more closely, and with the aid of some magnifying power. For the sake of simplicity it will be convenient to select first a piece of one of the timbers known as "deal" (firs, pines, &c.), and to observe it in the same direction as we commenced with, *i.e.* to examine a so-called transverse section.

The microscope will show us a figure like that in the woodcut (Fig. 3). There are to be seen certain angular openings, which are the sections of the long elements technically called *tracheides*, shown in elevation in Fig. 4. It will be noticed that whereas along some parts of the section these openings are large, and as broad in one direction as in the other, in other parts of the section the openings are much smaller, and considerably elongated in one direction as compared with the other. The band of small openings naturally looks more crowded and therefore darker than the band of larger openings, and it is to this that the differences in the shading of the annual rings in Fig. 2 are due. But it is not simply in having larger lumina or openings that the dark band of tracheides is distinguished from the lighter one: the walls of the tracheides are often also relatively thicker, and obviously a cubic millimetre of such wood will be denser and contain more solid substance than a cubic millimetre of wood consisting only of the larger, thin-walled tracheides. It is equally obvious that a large block of wood in which the proportion of these thick-walled tracheides with small lumina is greater (with reference to the bands of thin-walled tracheides) will be closer-grained, and heavier, than an equal volume of the wood where the thin-walled tracheides with large lumina predominate.

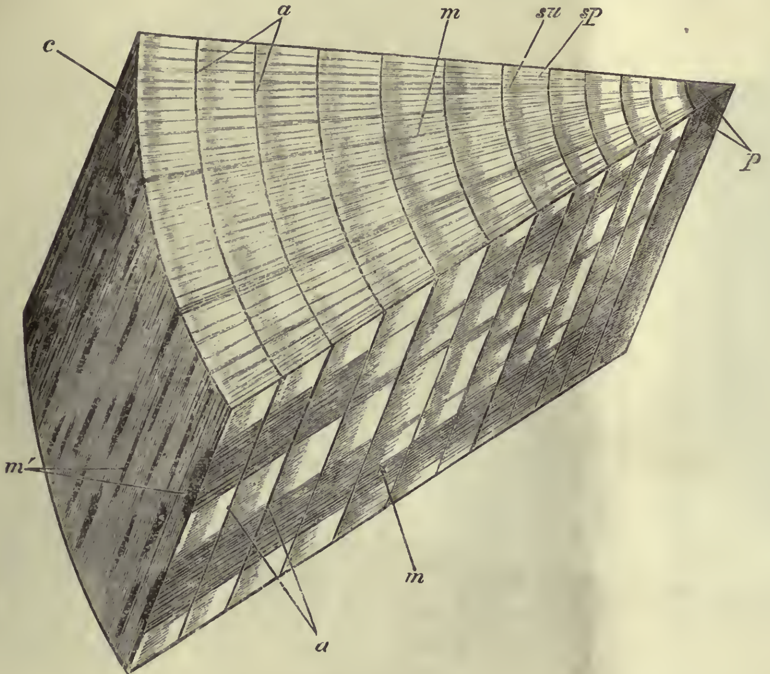

FIG. 2.

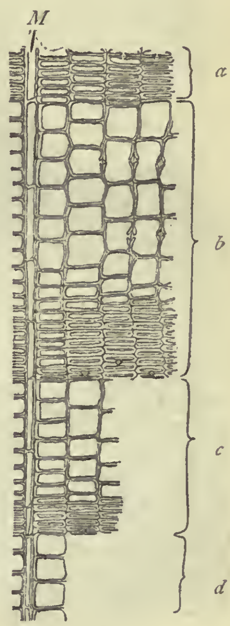

FIG. 3.

FIG. 2.—Portion of segment of wood from a log such as Fig. 1, supposed to be slightly magnified. *a*, annual ring; *m*, medullary rays; *m′*, the same in vertical section; *c*, the boundary line between one annual ring and another; *su*, autumn wood; *sp*, spring wood; *p*, the pith.

FIG. 3.—Portions of four annual rings from a thin transverse section of the wood of a Conifer, such as the Spruce-fir. *M*, a medullary ray; *b* and *c* show the entire breadth of two annual rings; *a*, autumn wood of an annual ring internal to *b* (and therefore older than *b*); *d*, spring wood of an annual ring external to *c* (and therefore younger than *c*). Bordered pits are seen in section on some of the tracheides. Magnified about 100 times.

Returning now to the section (Fig. 3), it is to be observed that the differences in the zones just referred to enable us to distinguish the so-called "annual rings." The generally accepted explanation of this is somewhat as follows. In the spring-time and early summer, the cambium-cells begin to divide, and those on the inner side of the cylinder of cambium gradually become converted into tracheides (excepting at a few points where the cells add to the medullary rays), and this change occurs at a time when there is (1) very little pressure exerted on the inner parts of the trunk by the cortex and corky bark, and (2) only comparatively feeble supplies are derived from the activity of the leaves and roots, in the still cool weather and short days with little sunlight. In the late summer, however, when the thickened mass of wood is compressed by the tightened jacket of elastic bark which it has distended, and the long, hot, bright sunny days are causing the numerous leaves and roots to

supply abundance of nutriment to the growing cambium-cells, it is not surprising that these cells cannot extend themselves so far in the radial direction (*i.e.* in a line towards the centre of the compressed stem), and that their walls are thickened by richer deposits of woody material supplied quickly to them.

As the winter approaches, the cambium ceases to be active, and it then remains dormant for several months. When its cells are awakened to renewed growth and division in the following spring, they at once begin to form the tracheides with thin walls and large lumina, and it is the sharp contrast thus displayed between the newly-formed tracheides with thin walls and large lumina, and the compressed denser ones on which they suddenly abut, that produces the impression of the "annual ring."

It is now time to attempt to give some clearer ideas of what this "cambium" is, and how its cells become developed into tracheides. But first it is necessary to point out that each tracheide is a long, more or less tubular and prismatic body, with bluntly tapering ends, and the walls of which have certain peculiar markings and depressions on them, as seen in Fig. 4. We cannot here go into the important signification and functions of these markings and depressions however, since their study would need an article to themselves. It must suffice for the present to state that the markings have reference to the minute structure of the cell-walls, and the depressions are very beautiful and complicated pieces of apparatus to facilitate and direct the passage of water from the cavity of one tracheide to that of another. Now, the cambium is a thin cylindrical sheet of cells with very delicate walls, each cell having the form of a rectangular prism with its ends sharpened off like the cutting edge of a carpenter's chisel: this prism is broader in the direction coinciding with the plane of the sheet of cambium—*i.e.* in the tangential direction, with reference to the trunk of the tree—than in the

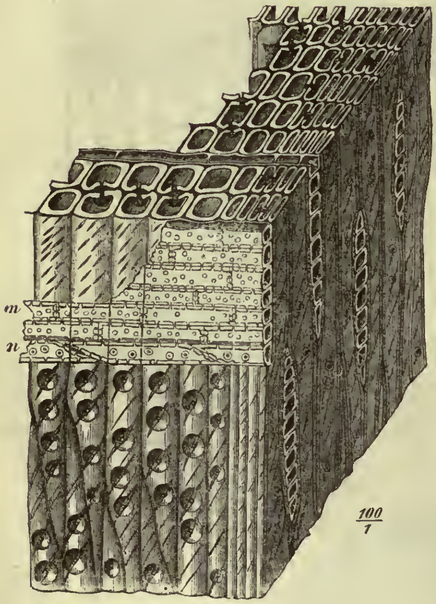

Fig. 4.

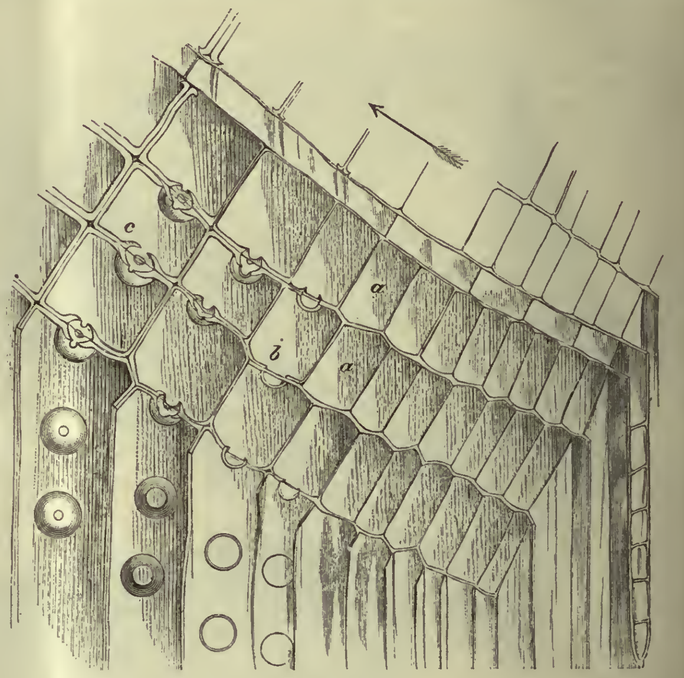

Fig. 5.

Fig. 4.—A small block of wood from a spruce-fir, supposed to be magnified about 100 times, showing elevation and sectional views of the tracheides of the autumn (to the right) and spring wood, and medullary rays (*m n*) running radially between the tracheides. (After Hartig.)

Fig. 5.—Portion of cambium of a fir, showing the development of the young wood tracheides from the cambium-cells. The arrow points to centre of the stem. The cambium-cells at length cease to divide, and the walls become thicker (*a*), except at certain areas, where the bordered pits are developed (*b* and *c*). To the right is a medullary ray. Highly magnified, and the contents of the cambium-cells omitted for clearness.

direction of the radius of the stem; and the chisel-edge must be supposed to run in the direction parallel to that of a medullary ray, *i.e.* radially. From the first, each cambial cell contains protoplasm and a nucleus, and is capable of being nourished and of growing and dividing. It is only at or near the tips of the branches, &c., that these cambium-cells are growing much in length, however; and in the parts we are considering they may be for the most part regarded as growing only in the radial direction; more rarely, and to a slight extent, in the tangential direction also, as the circumference of the cylinder enlarges. After a cambial cell has extended its walls by growth in the radial direction to a certain amount, a septum or division wall arises in the longitudinal tangential plane, and two cells are thus formed in place of one: this process of division may then be repeated in each cell, and so the process goes on. This is not the place to lay stress on certain facts which show that a single layer of cells initiates the division: it suffices to point out that by the above process of division of the cambial cells there are formed radial rows of cells, as indicated in Fig. 5, where the arrow points along a radius towards the centre of the stem. It is true such radial rows of cells are also developed in smaller numbers towards the outside of the cambium cylinder (*i.e.* to add to the cortex), but we are only concerned with the wood, and therefore only regard those cells which are developed on the inside (*i.e.* towards the centre of the stem). After a time the oldest of these cells (*i.e.* those nearest the centre of the stem) cease to divide, and undergo changes of another kind: the process of division is still going on in the younger ones, however; and so the radial rows are being extended by additions of cells at their outer ends. Of course, this is normally proceeding along the whole area of the cylindrical sheet of cambium, and therefore over the whole of the stem and roots, with their branches.

Confining our attention to one of the innermost, oldest cells of the cambium, which has ceased dividing (*aa* in Fig. 5), we find that it enlarges somewhat in the radial direction, and then its hitherto very thin walls become thicker; in fact, the protoplasm in its interior absorbs food-materials, and changes them into a peculiar substance which it plasters or builds on to the inner sides of the cell-wall, so to speak, until the wall is much thicker. This thickening process is withheld at certain places only—the thin depressions already referred to. Two chief changes result now: (1) the whole of the living contents of the young wood-cell gradually become used up, and eventually disappear without leaving any trace; and (2) the thickening substance built on to the inside of the walls undergoes changes which convert it into true wood-substance—in botanical language, the walls become lignified. The cells *b* and *c* in Fig. 5 illustrate what is meant.

During all these changes, which occupy several or even many hours or days, according to circumstances, it will be observed that the definitive shape of the cell is gradually completed, and then alters very little: the prismatic cambium-cell has become a prismatic tracheide, with thicker, lignified walls, and containing air and water (with minute quantities of mineral substances dissolved in it) in place of protoplasm and nutritive substances. It is not necessary here to speak of other and more subtle changes which cause slight displacements, &c., of these cells.

If I have succeeded in making the chief points in this somewhat complicated process clear, there will be little difficulty in explaining what occurs in other parts of the cambium-cylinder. The cambium-cells which happen to stand in the same radial row as the cells of a medullary ray, simply go on being converted into cells of the medullary ray, instead of into tracheides; cells which differ from the tracheides chiefly in retaining their living contents and nutritive materials—*i.e.* substances like starch, proteids, sugars, &c., which are used as food by the plant. Again, those cells of the cambium which are divided off on the outer side of the cylinder (they are always fewer in number) are gradually transformed into elements of the cortex, and finally enter into the composition of the bark proper.

Now and again, but much more rarely, a radial row of cambial cells which, from their position, it would appear should be converted into tracheides of the wood, alter their destiny, so to speak, and become the originators of a new medullary ray. But I must pass over these and some other minor peculiarities, and refer to the illustrations for further details.

If now, instead of a log of deal, or coniferous wood, we direct attention to the timber of a dicotyledonous tree, such as the oak, ash, beech, chestnut, poplar, &c., the differences in detail will not be found very great in relation to the broad features here under consideration. Turning again to Fig. 1, it would be possible to select a cut log of any of these timbers which presented all the salient characters there exhibited. The bark would present external differences in detail—such as in roughness, colour, thickness, &c.—but it could still be described, as before, as a more or less corky jacket around the whole of the wood: the cut face would show the timber marked by more or less numerous and prominent "annual rings," traversed by smaller or larger medullary rays, radiating from the central pith, and passing across the cambium to the cortex. Moreover, cracks would be apt to form on exposure, as before; the opening occurring along the lines of medullary rays—lines of weakness.

Again, if we cut a segment of the wood, like Fig. 2, the chief features would present themselves as there shown, and the lines of demarcation indicating the annual rings would be found to be due to the sharp contrast between the spring wood and the autumn or summer wood, as before.

On closely examining a transverse section of such a piece of timber, however, we should find differences which at first sight appear profound, but which on reflection and comparison turn out to be of more relative significance, from the present point of view, than might be expected.

Selecting a given example, that of the beech for instance, the first difference which strikes us (Fig. 6) is a number of relatively very large openings on the transverse section: these are the vessels—pitted vessels—long tubular structures which are not formed by the cambium of the conifers. Between these vessels are much more numerous elements with very small lumina and thick walls: the latter are the wood-fibres proper, and have to be technically distinguished from the apparently somewhat similar wood-tracheides of the pines, firs, &c. Here and there, scattered in small groups, are certain rows of shorter cells, which, however, are not very numerous in the beech: they are called wood-parenchyma (Fig. 6, *wp.*), and occur particularly in the vicinity of the vessels.

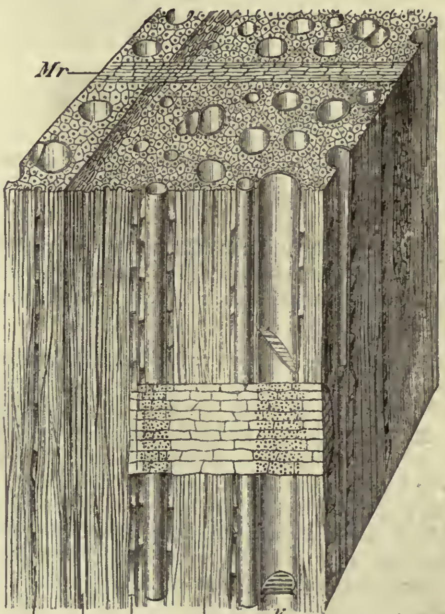

Fig. 6.—A piece of wood from a dicotyledonous tree (beech), supposed to be magnified about 100 times. *Mr*, a medullary ray running across the transverse section: the dark band crossed by this ray is the autumn wood (*a*), formed of closely-crowded wood-fibres and tracheides; *v*, a large vessel in section: others are seen also—they are smaller and fewer towards the autumn wood; *a′*, wood-fibres, of which most of the timber is composed; *wp*, wood-parenchyma cells.

It is beside the purpose here to describe in detail the histology of the beech-wood, and reference may be made to the figures for further particulars. It may suffice to say that all the elements—cells, fibres, and vessels—are formed as before by the gradual development of cambium, cells; and the same is true, generally, of the medullary rays here that is true of those of the pines and firs, &c.

Attention is to be directed to the fact, which is here again evident, that the line of demarcation between any two "annual rings" is due to the sudden apposition of non-compressed elements upon closely-packed and apparently compressed elements: the latter were formed in the late summer, the former in the spring. Moreover, the spring wood usually contains more numerous vessels, with larger lumina than the autumn wood: in this particular case, again, the fibres of the autumn wood are darker in colour. It should be stated, however, that many dicotyledonous trees show these peculiarities much more clearly than the beech; others, again, show them less clearly.

Now it is obvious that, other things being equal, the spring wood, with its more numerous and larger vessels, and its looser tissue generally, will yield more readily to lateral pressure and strains than the denser autumn wood; and the like is true of the pines and firs—the closely-packed, thick-walled tracheides of the autumn wood furnish a firmer and more resistant material than the larger, thinner-walled tracheides of the spring wood. To this point we shall have to return presently.

H. MARSHALL WARD.

(*To be continued.*)

NOTES.

WE deeply regret to announce the death of Prof. Balfour Stewart, one of our most eminent men of science. Last Friday morning he left the Owens College, apparently in his usual health and in good spirits, intending to spend the holidays at his Irish home. He died on Sunday night. Next week we shall have something to say about his character and work.

THE death of Carl Langer, the well-known Professor of Anatomy at the University of Vienna, is announced. He was in his sixty-eighth year.

DR. ARTHUR FARRE, F.R.S., died on the 17th inst., in his seventy-seventh year. He was elected a Fellow of the Royal Society in 1839.

THE Royal Society has been admitted to the number of those public bodies to which is conceded by prescription or otherwise the privilege of presenting their addresses to the Sovereign on the throne.

THE Curatorship of the Natural History Department of the Science and Art Museum, Dublin, rendered vacant by the resignation of Mr. A. G. More, has just been filled by the promotion of Dr. R. F. Scharff, who had been one of the assistants in the Museum for some months. Dr. Scharff has already proved himself to be a diligent student of zoology in Edinburgh, where he took the degree of Bachelor of Science. In London he studied under Prof. Ray Lankester, and worked in the British Museum for some time under the Director, Prof. Flower, F.R.S., and he obtained the degree of Doctor of Philosophy at Heidelberg University.

MR. JOHN M. THOMSON has been appointed to the Chair of Chemistry in King's College, vacant through the death of Prof. Bloxam.

AT the Central Institution, Exhibition Road, South Kensington, Dr. A. K. Miller, Demonstrator and Assistant in the Chemical Research Laboratory, will deliver, during the spring term, a course of ten lectures on the chemistry of oils and fats. The course will be delivered on Mondays at 4 p.m., and will begin on January 23, 1888.

THE third annual meeting of the American Association for the Advancement of Physical Education was held at Brooklyn on November 25. It was well attended. Papers were read by Prof. Edward Hitchcock, of Amherst College, who presided; by Prof. E. H. Fallows, of the Adelphi Academy; and by Prof. J. W. Seaver, of Yale College.

Science (December 9, 1887) notes, as a fact which may be of interest to Americans, that in England the point of view of those who argue in favour of technical education is almost exclusively the economic. "But little is heard," it says, "of the educational nature of manual training." Speaking of the state of things in the United States, *Science* says:—"There is now, as is well known, a very general movement throughout this country in favour of what is known as manual training in education. After much misapprehension and tedious explanation, the leaders of this movement have finally managed to make the educational public understand that they advocate manual training mainly for its educational value, and only incidentally for the economic benefits which will undoubtedly flow from it."

THE twentieth annual meeting of the Kansas Academy of Science was held in the Capitol Building, Topeka, on October 26, 27, and 28. *Science* says that there was an excellent attendance of members, but that the local attendance was not quite equal to that of last year. The papers read, according to *Science*, were unusually valuable. The annual meeting next year will be held in Wichita, in October.

THE tenth general meeting of the German Society of Analytical Chemists was held at Frankfurt, on November 30. Dr. Schmitt, of Wiesbaden, was President.

THE tenth meeting of the German Geographical Society will be held at Berlin next Easter. In future the meetings will be held only once in two years.

FIFTY shocks of earthquake are reported to have occurred at Silveric, in Dalmatia, on November 29. On the same day, at 7.30 a.m., severe shocks occurred at Oran, Mascara, and Relizante, in Algeria.

ON the evening of November 21, from 8.30 p.m. to about 9, a remarkable luminous phenomenon, viz. a broad band of light right across the sky, was seen throughout the whole of central and southern Sweden. It caused much speculation, chiefly on account of its luminous immobility. Dr. N. Ekholm, of the Upsala Meteorological Observatory, and well known for his researches on the aurora borealis at Spitbergen, has now pronounced the phenomenon to be a so-called auroral band. Dr. Ekholm states that such bands are very uncommon in Sweden, but that they are often seen at Spitzbergen. He saw the phenomenon during a journey from Stockholm to Upsala, at 8.45 p.m., and noted its position. The band ran then just north of the northernmost stars in Orion, through Aldebaran, then a little south of the Pleiades, further through the Ram, and then a little north of the two southernmost stars in the square of Pegasus. He calculates its height above the earth at about 80 miles, its zenith being perpendicular above the two provinces of East and West Gothia. The bands moved from north to south at the rate of about 50 metres per second. In Upsala it seemed south of the zenith. Dr. V. C. Gyllenskiöld made similar observations at Upsala. Dr. Ekholm invites all who may have observed the phenomenon to communicate their observations to him in the interests of science.

ON the afternoon of November 26, at 4.30, a splendid meteor was seen at Laurvik in the Christiania fjord. It went from east to west, and apparently low in the horizon. In spite of the moonlight its tail was visible for some seconds afterwards.

ONE morning last week, the Teusfjord, a little to the north of Bergen, on the west coast of Norway, was covered with ice three-quarters of an inch thick, as far as the eye could reach. Ice, in consequence of the influence of the warmth of the Gulf Stream, has hitherto been unheard of on the west coast of Norway.

Symons's Monthly Meteorological Magazine for December contains an investigation of what was reported in the newspapers to have been an earthquake-shock in Central England on November 20 last. At the more western stations the reporters spoke chiefly of noise, and at the eastern ones of earth tremor. From evidence collected, it appears that the disturbance, as Mr. H. G. Fordham pointed out in NATURE last week (p. 151), was caused by the explosion of a large meteor. Further particulars

are requested, especially as to the locality where the meteor burst, which seems likely to have been between Thame and Abingdon.

THE Pilot Chart of the North Atlantic Ocean for December reports the occurrence of two interesting phenomena. (1) The formation of a very large waterspout on October 6 in latitude 39½° N., longitude 69° W., during a thunder squall. The lower end of the spout did not reach the surface of the ocean. Water could be seen rushing down through the centre of the funnel and ploughing up the surface of the sea to a height of about 50 feet. (2) One of the rare and inexplicable cases of globular lightning. On November 12, at midnight, near Cape Race, a large ball of fire seemed to rise out of the sea to a height of about 50 feet, coming against the wind close up to the ship, and then running away to the south-east, lasting altogether about five minutes.

THE Meteorological Report published for the year 1886 by the Surveyor-General of Ceylon shows that rainfall observations are now taken at eighty-three stations. General observations are made at sixteen stations. The Report contains a map showing the mean annual rainfall of the island, and a diagram of the mean monthly fall at the principal stations. An important discussion of the Ceylon rainfall observations will be found in the Quarterly Journal of the Royal Meteorological Society for October last.

THE Russian Government does good service to meteorology by publishing observations taken for several hours daily on some selected cruises of its men-of-war. A volume has just been issued containing the observations of three such voyages, being Nos. 52-54 of the series. The information is rendered more available for ready use by the weather observations being expressed in the international symbols, and by the data being printed on one side only, to allow of being cut up and pasted in districts as required.

IT is reported from India that, in connection with a plan for improving the system of storm-warnings, new meteorological stations are to be opened, on the Coromandel coast, at Bimlipatam, Nellore, and Cuddalore, and one on the Burmah coast, probably at Tavoy. Mr. Elliott, Superintendent of the Bengal Meteorological Department, was to leave on an inspection tour to visit the coast stations, and to select sites for the new observatories.

THE *Observatory* will in future be edited by Mr. Turner, of Greenwich Observatory, and Mr. Common, of Ealing.

A FLORA of Hertfordshire by the late Alfred R. Pryor, edited by Mr. B. Daydon Jackson, with notes on the geology, climate, and rivers of the county, by Mr. John Hopkinson, will be published in a few days by Messrs. Gurney and Jackson, Mr. Van Voorst's successors. The book will consist of about 600 pages with a map.

THE twenty-third annual volume of the *Zoological Record* will be issued shortly. This valuable book of reference, which was established by Mr. Van Voorst, under the editorship of Dr. Günther, has been for some years supported by an Association. It is now taken over by the Zoological Society. Messrs. Gurney and Jackson will continue to publish the volumes.

MESSRS. GEORGE PHILIP AND SON have in the press, and will shortly publish, "Emin Pasha in Central Africa: Letters and Journals," collected and annotated by Dr. G. Schweinfurth, Dr. Ratzel, Dr. G. Hartlaub, and Dr. Felkin. The work has been translated from the German by Mrs. Felkin. It is illustrated with a portrait, and with two maps specially compiled by E. T. Ravenstein.

A SIXTH edition of Prof. Alleyne Nicholson's "Introductory Text-book of Zoology" (Blackwood) has just been issued. The book is intended for the use of junior students. It has been thoroughly revised, and the author explains that the general arrangement of certain of the larger groups of animals has been altered in accordance with the views now most generally accepted by naturalists. Some of the illustrations have been changed, and a few new engravings have been added.

WE have received from Mr. F. Enock some "Autocopyist" pen-and-ink sketches of bodies and parts of insects, together with examples of the prepared mounts of the objects delineated. The latter call for no special comment. The drawings, however, are exceedingly clear and well printed, scrupulously accurate, and highly commendable. The admiration of the beautiful in Nature must precede the study of the more useful; and, this being so, we can heartily recommend these drawings to the legion of microscopical *dilettanti*. Mr. Enock is practical in his work in that he introduces the Hessian fly, together with a sketch of the infected barley. By way of giving the brief notes which accompany the sketches an authoritative air, he introduces occasional bibliographical references. As pertaining to the aforenamed pest, an important paper by Prof. Fream, read before the British Association this autumn, and duly reported in these pages, may be recommended to Mr. Enock's notice.

M. VAYSSIÈRE, of Marseilles, has begun what promises to be an important publication—an atlas of the anatomy of invertebrates. The first quarter of the book has already been issued.

MESSRS. MACMILLAN AND CO will publish early in January a revised and extended edition of the well-known "Practical Biology" of Prof. Huxley and Dr. H. N. Martin. The work of revision has been carried out by Messrs. G. B. Howes and D. H. Scott, of the Normal School of Science. Besides other improvements, including the addition of the Earthworm and the Snail in the series of animal, and of *Spirogyra* in the series of vegetable, types, the order of the subjects is completely changed. Whereas in the original edition the lowest forms of life were first dealt with, and then the rest in ascending scale, the course is now reversed, beginning with the Frog and proceeding thence to the less familiar regions of invertebrate organizations until the borderland between animals and plants is reached, and a natural ascent can be made to the most complicated vegetable organisms. Prof. Huxley explains in the preface to the new edition that after two or three years' trial of the road from the simple to the complex he became thoroughly convinced that the way from the known to the unknown was easier for students.

AN exhibition embracing every branch of science or manufacture connected with the art of photography will be opened at the Crystal Palace in February next. Valuable exhibits have already been promised, and there is every reason to believe that the collection of pictures and apparatus will be larger than at any previous exhibition, while the classification will be far more complete. Medals and certificates will be awarded for competitive photographic lantern slide entertainments.

WE are informed that the Committee appointed by the Pari Academy of Medicine to investigate the influence of fluorhydric acid on tuberculosis has reported very favourably on the subject. It seems that the Bacilli of tuberculosis are speedily destroyed by minimal proportions of fluorhydric vapours. This fact is an important one for the therapeutics of that very common and fatal disease, tuberculosis.

THE additions to the Zoological Society's Gardens during the past week include a Common Wolf (*Canis lupus*), European, presented by Mr. C. S. Hardy; a Spotted Crake (*Porzana maruetta*), British, presented by Mr. F. W. Proger; two Golden Plovers (*Charadrius pluvialis*), British, purchased.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1887 DECEMBER 25-31.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on December 25

Sun rises, 8h. 7m.; souths, 12h. 0m. 14·9s.; sets, 15h. 53m.: right asc. on meridian, 18h. 15·0m.; decl. 23° 24′ S. Sidereal Time at Sunset, 22h. 8m.

Moon (Full on December 30, 8h.) rises, 13h. 32m.; souths, 20h. 31m.; sets, 3h. 41m.*: right asc. on meridian, 2h. 46·7m.; decl. 10° 40′ N.

THE U.S. COMMISSION OF AGRICULTURE.[1]

"RESOLVED by the Senate and House of Representatives of the United States of America, in Congress assembled, That there be printed 310,000 copies of the Annual Report of the Commissioner of Agriculture for the year 1885; 200,000 for the use of the Members of the House of Representatives, 80,000 for the use of the Members of the Senate, and 30,000 copies for the use of the Department of Agriculture.

"Sec. 2. That the sum of 200,000 dollars is hereby appropriated out of money in the Treasury to defray the cost of the publication of the said Report."

If the British Government desires to assist poor languishing agriculture, it would be well for it to look across the Atlantic Ocean for suggestions as to possible action. A "Commissioner of Agriculture" and an Annual Report from him is in itself enough to arrest attention. The very gilt letters on the back of this volume supply a text upon which a profitable and edifying sermon might be preached. The subject-matter of the Report, its practical or unpractical nature, the sort of topics handled, and the manner of their handling, all ought to arouse curiosity in the minds of those who doubt the utility of Commissions, and prefer *laissez faire* to stirring up with the long pole.

A more scattered flock than the agriculturists of Great Britain it would be difficult to find. Sheep without a shepherd, soldiers without a leader, a fleet without sailing orders, are the metaphors we should use if it were our purpose to portray their present condition. It is not so in America. There the interests of agriculture are watched by a Department of Agriculture, and the splendid Report of the proceedings of this Department serves as a mouth-piece of the whole agricultural community, and exercises the functions of a heart in keeping up a healthy circulation of knowledge and a brain in receiving impressions from all parts of the body agricultural. No wave of pleasurable sensation arising from salubrity of climate or rise of values but causes a smiling paragraph. No twinge of pain caused by insect attack or disease but is at once chronicled and investigated in this excellent Department. The cost is all defrayed by the Government, who are not afraid to spend 200,000 dollars on the mere publication of the Report. Whether the Report is worth the immense sums of money that its material with the large staff of persons employed in collecting the same must have cost is a question of much importance, and not altogether easy to answer. One thing, however, we may be certain of: that if it pays the American Government to undertake the investigation of problems connected with the productive powers of Nature, still more would it pay us with our complicated agriculture and extensive system of cultivation. It might be said in extenuation of our supineness with regard to agricultural science that we have an Agricultural Department of the Privy Council. So far as this Department may prove a nucleus for further expansion it is good, but we cannot conceal from ourselves the narrowness of the scope of our Agricultural Department as compared with the breadth of the aims and objects of the American Agricultural Department. The energies of our Department are chiefly devoted to what is included in the Report before us as the Bureau of Animal Industry, but with this great difference: the English Agricultural Department deals chiefly with inspecting and regulating the ports of debarkation, reporting on outbreaks, and proclaiming infected districts. It is intimately connected with and assisted by the police. The American Bureau of Animal Industry deals in rules and regulations for the suppression and extirpation of contagious diseases, but in addition spends large sums upon investigations into the nature, causes, and remedies of diseases. Its Reports are replete with information as to liquid cultures of the Bacterium of swine fever and other diseases. The American Government have not only set themselves the task of preventing the spread of disease, but are doing excellent work in tracking diseases of all sorts to their source, with a fair and improving prospect of being able to stop their devastations at the fountain-head. Not only is this the case with regard to the diseases of animals, but also of plants, under the sections respectively headed "Report of the Botanist" and "Report of the Microscopist."

Before endeavouring to lay before the readers of NATURE any of the facts recorded in this deeply interesting volume, I will mention the various sections under which information is collected and investigations are prosecuted, feeling confident that by so doing I shall show the many sides from which agriculture obtains direct assistance from the progress of pure science. First in order stands the Report of the Superintendent of Gardens and Grounds, containing valuable information upon mildews and blights, the peach-leaf blister, cracking of pears, and the potato-disease. Next comes the Report of the Chief of the Seed Division, dealing with crossing and hybridization, the production of new varieties of wheat by cross-fecundation, improvement by selec-

[1] "Report of the Commission of Agriculture, 1885." (Washington Government Printing-Office.)

tion and cultivation, vitality of seeds, germination of seeds, and changing seed. The Report of the Botanist consists in an illustrated descriptive list of certain economic plants, and a chapter upon the fungous diseases of plants. Next comes the Report of the Microscopist, dealing with textile fibres, parasites of domestic fowls, crystals of fats—butter, beef, and lard—beautifully illustrated with coloured plates, and highly interesting in connection with the adulteration of butter. I must content myself with a mere enumeration of the Reports of the Chemist, the Chief of Division of Forestry, the Entomologist, the Statistician, the Chief of the Bureau of Animal Industry, a Report on wheat-culture in India, and truck-farming, "or the growing at the South, exclusively for the Northern markets, as a distinct business, of all (or a selection of) such fruit and vegetables as would be likely to arrive at their destination in good condition."

Before concluding this first notice, I must mention the fine manner in which the work is illustrated by tables, diagrams, maps, engravings, and coloured plates. The illustrations of fat-crystals have been already mentioned. Other illustrations are a delicately-tinted and beautifully-drawn collection of twelve edible mushrooms common in the United States; a coloured picture of the transformation of *Cicada septemdecim*, taking place in every stage, on a leafy branch of oak; and splendidly-executed coloured plates illustrative of verminous bronchitis and of ulcerated cæcum in the Section of Animal Industries.

To an Englishman, probably the most interesting portion of the book will be the Report of the Statistician, with its tables of exports and imports, area, and productive power of the United States. The control which the States exercise over the wheat trade of the world is indicated by a diagram showing that, as the yield per acre of the States rises, the prices of wheat all over the world fall; and as the average yield diminishes the prices rise. This correspondence between yield and price is even more precise in the case of oats and maize than in the case of wheat, because, as the Statistician remarks, "we make our own prices for corn and oats, while Liverpool has much to do with the price of wheat."

A very striking diagram, which cannot fail to be of deep interest to those who feel themselves cramped for room in over-crowded England, is one showing the proportion of forests, farms, and unimproved or waste lands in the United States. The vast and almost appalling extent of the first and last sections shows the inexhaustible resources of the country. In Texas, California, Dakota, Montana, New Mexico, Arizona, Nevada, Colorado, Wyoming, Oregon, Idaho, Utah, Kansas, Minnesota, Nebraska, and even Washington, the amount of cultivated or farmed land is quite insignificant compared with the vast tracts of forest and of unreclaimed land. One cannot but reflect upon the fact that a country so wealthy in the raw material of the soil should yet find it advisable to spend money lavishly upon scientific investigation of agricultural difficulties, while England, with her restricted area and dense population, should allow her agriculture to drift, as though its welfare were of no importance, or its downfall no cause of anxiety.

JOHN WRIGHTSON.

WEIGHTS AND MEASURES.

THE Annual Report of the Standards Department of the Board of Trade on its proceedings and business during the past year has been recently issued. It would appear that the Department has of late been pressingly engaged on ordinary work under the several Acts of Parliament which govern its proceedings, but there are some matters of scientific interest referred to in the Report to which we might invite attention.

Standards of various kinds, for determining capacity, length, weight, and volume, continue to be verified for official purposes, or for private use in aid of scientific research or otherwise, without fee or any charge.

Further representations have been made as to the want of a standard hydrometer, accurately adjusted to the legal units of weight and measure in force in this country, for determining the specific gravities of liquids heavier than alcohol.

The sanction of the Treasury has been obtained to the purchase, at an estimated cost of £1000, of copies of the new metric standards of length and weight, which are being prepared at Paris, under the directions of the Comité International des Poids et Mesures.

An exhaustive series of comparisons of the geodetic standards of New South Wales with those of the Board of Trade and the Ordnance Survey has been made by Mr. H. C. Russell, Government Astronomer, Sydney, and Mr. H. J. Chaney, of the Standards Department; of which comparisons a separate Report has been prepared.

In a memorandum on the accurate definition of metrological units, which is attached to the Report, it is pointed out, with regard to metric units, that the relation of the metric unit of weight, the kilogramme, to the metric units of length and capacity is not based on a natural constant, as is generally taught. If the kilogramme prototype were lost, for instance, it would not be restored by reference to the weight of water contained in the cubic-decimetre. The latest experiments have shown that the cubic-decimetre of distilled water ($t = 4°$ C.) weighs, under given conditions, nearly 100 milligrammes less than a true kilogramme weighs. Hence the value of the unit of capacity, the litre, depends on the kilogramme weight, and not on the metre measure. There is *de facto*, it is stated, no more scientific relation between the metric unit of weight, the kilogramme, and the metric units of length and capacity, the metre and litre, than there is between the present conventional metre and the original natural standard of one ten-millionth part of the Paris meridian.

It is curious to note, session after session, how large an amount of purely technical work continues to be added to the ordinary duties of local officers such as inspectors of weights and measures, inspectors of gas, inspectors of petroleum, &c. During the past year we notice, for instance, that the Legislature has, amongst other things, made it necessary for all weighing-machines used at mines in determining colliers' wages, as well as machines used in weighing cattle to be examined and tested by the local inspectors, many of whom are simply constabulary officers. Now the testing of a compound lever weighing-machine requires some special knowledge, but many of the officers have, it would appear, no technical qualification whatever for such duty. Hence the duties imposed by the Legislature are in many districts carried out in an indifferent and perfunctory manner; and another practical instance is afforded of the necessity for increased technical education of that class from which the above local officers are drawn. Without requiring, as in Germany, that every such local officer—as an inspector of weighing-machines—should pass a technical examination, it would certainly appear to be desirable before such officer is appointed that the local authorities (as the County Justices and Town Councils) should see that he has had some proper scientific training.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The term has been very uneventful so far as the Natural Science School is concerned. There has been no new departure in scientific education, and no important conflict with the rest of the University. The most satisfactory feature of the term is the granting of £1200 to be expended during the next three years on the Pitt-Rivers Anthropological Museum. The collection has been enriched by the transference of a quantity of valuable objects from the Ashmolean Museum, and by private gifts; the arrangement and cataloguing of the whole collection is proceeding steadily under the superintendence of Mr. Balfour of Trinity.

Unfortunately Prof. Moseley's continued illness has made it necessary for him to apply for prolonged leave of absence. Dr. S. J. Hickson, Downing College, Cambridge, will act as his deputy next term.

The Millard Laboratory for Experimental Mechanics at Trinity is to be enlarged during the vacation by the addition of a lecture-room and drawing-room, which formed part of Mr. Bosanquet's Laboratory at St. John's.

CAMBRIDGE.—At the annual election of candidates not yet in residence, the following awards were made:—

Foundation Scholarships: H. H. Hough (£80, in Mathematics), St. Paul's School; A. G. Pickford (£60, in Mathematics and Physics), the Owens College, Manchester; E. F. Gedye (£50, in Mathematics), Leys School, Cambridge. Minor Scholarships: F. A. Leete (£50, in Mathematics), Wellingborough School; C. Robertson (£50, in Mathematics), Norwich School. Exhibitions: E. W. MacBride (£50, in Natural Science), Queen's College, Belfast; V. M. Turnbull (£33 6*s*. 8*d*., in Mathematics), St. Bee's School. Sizarships: A. W. Cuff, in Natural Science; R. E. Baker, in Natural Science; W. N. Maw and G. F. J. Rosenberg, in Mathematics.

SCIENTIFIC SERIALS.

THE *Quarterly Journal of Microscopical Science* for November 1887 (volume xxviii. part 2) contains the following papers:—On the development of *Peripatus novæ-zealandiæ*, by Lilian Sheldon, Bathurst Student, Newnham College, Cambridge. (Plates 12 to 16.) The ripe ova are large when compared to those of *P. capensis* or *P. edwardsii*, measuring about 1·5 mm. in their long axis; this size seems due to the enormous amount of food-yolk with which the eggs are charged; the segmentation is on the centrolecithal type; the protoplasm is in the form of a reticulum; there are no traces of cell outlines. The various stages, from a want of material, were not in all cases noted, but the authoress with great ability traces many stages of the development of the embryo, until that in which the food material is completely absorbed, so that the embryo lies just within the vitelline membrane and egg shell. We trust that she will continue her investigations as fresh specimens are obtained, until she is enabled to write the whole life-history of this very interesting form.—On some points in the anatomy of Polychæta, by J. T. Cunningham. (Plates 17 to 19.) This paper gives the results of some investigations into certain Polychæte structures; on the nephridia and gonads, with a criticism of Cosmovici's paper on the "Glandes genitales et Organes segmentaires des Annelides Polychetes"; on the cardiac body, and on the neural canals.—On Temnocephala, an aberrant monogenetic Trematode, by William A. Haswell. (Plates 20 to 22.) Four species were found; one, *Temn. novæ-zealandiæ*, found on *Paranephrops setosus*, from rivers of New Zealand; a second, *Temn. minor*, on *Astacopsis bicarinatus*, from streams of New South Wales; a third, *Temn. quadricornis*, on *Astacopsis franklinii*, from northern rivers of Tasmania; and a fourth, *Temn. fasciata*, on *Astacopsis serratus*, streams of New South Wales. Diagnoses of these species are not given, but it is possible to distinguish them by the comparative details given of their structure; they seem to differ from the type species of the genus, *T. chilensis*, Gay; and Wood-Mason is probably wrong in thinking that this latter species is to be found in New Zealand. When undisturbed, the Temnocephala adhere to the surface of the crayfish by means of a sucker.—Notes on Echinoderm morphology, No. xi.: on the development of the apical plates in *Amphiura squamata*, by Dr. P. Herbert Carpenter, F.R.S.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 8.—"The Post-embryonic Development of *Julus terrestris*." By F. G. Heathcote, M.A. Communicated by Adam Sedgwick, F.R.S.

With regard to the development of the cœlom and generative organs, I have obtained the following results. The somites divide into two parts, as described for *Strongylosoma* by Metschnikoff, one part remaining in the body and the other part projecting into the legs. The cavities in these two parts together constitute the cœlom. The part within the legs breaks up and the cells give rise to muscles. The part within the body passes dorsalwards along the thin sheet of mesoblast which unites it to its fellow of the other side, so that the two vesicle-like parts meet above the nerve-cord in the middle line. They join so as to form a single tube, the generative tube. The young ova, as well as the follicle cells surrounding them, are formed by cells proliferated from the walls of this generative tube. The body parts of the somites of the antennæ and mandibles break up and disappear, but those of the third pair of appendages give rise to the pair of salivary glands. There are two pairs of somites to each double segment.

In the development of the nerve-system, I find that there are two cerebral grooves formed as in *Peripatus*. They disappear early in the development. The ventral nerve-system, which at first consists of two separate cords united by a thin median part, undergoes a process of concentration which results in the presence of a single stout cord showing slight traces of its former double condition.

The heart is formed from mesoblast cells in the body-cavity. These cells, which were directly derived from the hypoblast in the early stages of development, form a network in the body-cavity. The heart is the result of a joining together of the meshes of this network, and thus is formed by the confluence of a series of spaces in the mesoblast, and has nothing to do with the development of the cœlom.

The body-cavity is a series of spaces between the gut and the body-wall, and is divided up by the mesoblast cells already referred to. It is distinct from the cœlomic cavities of the somites, and is therefore a pseudocœle.

The eye-spots are all formed in the same manner. The hypodermis thickens, and a cavity appears within it bounded by pigment. This cavity becomes a distinct vesicle. The front wall of the vesicle becomes very thin and furnishes the lens, while the cells of the back (*i.e.* most internal) wall and sides become elongated and form the retinal elements of the eye. The nuclei of the front wall become very faint and finally disappear.

The most striking feature of the development is the reduction of the ventral part of the young animal and the increase of the dorsal. In the just hatched animal the ventral region is nearly as large as the dorsal, and the legs are wide apart, having a distinct space between them. As development progresses the dorsal region is increased, while the ventral is contracted till the bases of the legs are close together. The corresponding concentration of the nerve-cord I have already mentioned. In a paper on *Euphoberia*, a Carboniferous Myriapod, Mr. Scudder points out that one of the principal points in which the genus differs from existing Diplopoda is the development of the ventral region. The relations of the dorsal and ventral regions of the body of the *Euphoberia* correspond exactly to the condition of the young *Julus*.

With regard to the double segments of *Julus*, Newport held that each double segment corresponded to two segments originally distinct which had fused together; subsequent writers have held that each double segment is a single segment which has developed a second pair of legs. Now considering the double segments with regard to the development as well as to the adult condition, we see that the mesoblastic segmentation is double, so are the tracheal, the nervous, and circulatory systems. The only part of these double segments which is single is the dorsal plate with its stink glands which arise as invaginations in it; this dorsal plate being so enlarged as to form a complete ring round the body of the adult. Looking at the palæontology, we find that in the Archipolypoda, a family including the Archidesmidæ, Euphoberidæ, and Archijulidæ, the dorsal plate did show distinct traces of a division. Therefore I think that each double segment represents two complete segments, the dorsal plates of which have fused together to make one plate.

Zoological Society, December 6.—Prof. W. H. Flower, F.R.S., President, in the chair.—Mr. Howard Saunders exhibited (on behalf of the Rev. H. A. Macpherson) a specimen of the Isabelline Chat (*Saxicola isabellina*) shot in Cumberland, being the first recorded occurrence of this species in Great Britain.—Prof. Bell exhibited and made remarks on specimens of the tegumentary glands from the head of the Rocky Mountain Goat (*Haplocerus montanus*).—A communication was read from Prof. H. H. Giglioli and Count T. Salvadori, containing notes on the fauna of Corea and the adjoining coast of Manchuria. The notes were founded on a large collection, principally of Vertebrates, made by order of H.R.H. Prince Thomas of Savoy, Duke of Genoa, whilst he was in command of the *Vettor Pisani*, on a voyage round the world, 1878–81. The collection was stated to be now deposited in the Royal Zoological Museum at Florence.—A communication was read from M. L. Taczanowski, containing a list of birds collected in Corea by M. J. Kalinowski between September 1885 and March 1887. A Woodpecker in the collection was considered to be new to science, and named *Thriponax kalinowskii*.—Prof. W. H. Flower read a paper on the Pygmy Hippopotamus of Liberia (*Hippopotamus liberiensis*), and its claims to distinct generic rank. The specimen of this animal in the National Collection possessed two incisor teeth on one side of the lower jaw. This and other considerations induced the author to question the advisability of separating it generically from *Hippopotamus*.—Mr. Francis Day, communicated a paper by Mr. J. Douglas-Ogilby, of the Australian Museum, Sydney, on a new genus and species of Australian Mugilidæ, which he proposed to designate *Trachystoma multidens*.—Mr. Day also read a second paper by Mr. Ogilby, giving the description of a new genus of Percidæ based on examples taken in the Gulf of St. Vincent, South Australia, which the author proposed to describe as *Chthamalopteryx melbournensis*.—A communication was read from Dr. M. Menzbier, of Moscow, describing a third

species of Caucasian Wild Goat. This he proposed to call *Capra severtzovi*, being the *C. caucasica* of Dinnik, but not of Guldenstaedt.—Mr. Blanford read some critical notes on the nomenclature of Indian Mammals, in which he treated of *Macacus ferox*, Shaw (*M. silenus*, auct., *nec* Linn.), *M. irus*, Cuv. (*M. cynomolgus*, auct., *nec* Linn.), *M. rhesus*, *Presbytes thersites* Blyth, *Semnopithecus chrysogaster*, *Felis bengalensis*, *F. jerdoni*, *Herpestes mungo* (*H. griseus*, auct., *nec* Geoffr.), *Vulpes vulgaris*, *V. alopex*, and the genera *Putorius*; *Mustela*, *Xantharpyia*, *Cynonycteris*, *Hipposiderus*, and *Phyllorhina*.

Geological Society, December 7.—Prof. J. W. Judd, F.R.S., President, in the chair.—The following communications were read:—A letter from H.M. Secretary of State for the Colonies, inclosing an account of recent discoveries of gold in the Transvaal.—On the age of the altered limestone of Strath, Skye, by Dr. Archibald Geikie, F.R.S. The remarkable alteration of the limestone of Strath into a white saccharoid marble, first described by Macculloch, has hitherto been regarded as an instance of contact-metamorphism in a rock of Liassic age. The various writers who have described the geology of the district have followed Macculloch in classing the whole of the ordinary and altered limestone with the Secondary series of the Inner Hebrides. The author, however, saw reason in 1861 to suspect that some part of the limestone must be of the age of the Durness Limestone of Sutherland—that is, Lower Silurian; and he expressed this suspicion in a joint paper by the late Sir R. I. Murchison and himself, published in the eighteenth volume of the Quarterly Journal of the Society. He has recently returned to the subject, and now offers lithological, stratigraphical, and palæontological evidence that the altered limestone is not Lias, but Lower Silurian. In lithological characters the limestone, where not immediately affected by the intrusion of the eruptive rocks, closely resembles the well-known limestones of the west of Sutherland and Rosshire. It is not more altered than Palæozoic limestones usually are. It contains abundant black chert concretions and nodules, which project from the weathered surfaces of the rock exactly as they do at Durness. These cherts do not occur in any of the undoubted Lias limestones of the shore-sections. The limestone lies in beds, which, however, are not nearly so distinct as those of the Lias, and have none of the interstratifications of dark sandy shale, so conspicuous in the true Liassic series. The stratigraphy of the altered limestone likewise marks it off from the Lias. There appears to be a lower group of dark limestones full of black cherts, and a higher group of white limestones with little or no chert, which may be compared with the two lower groups of the Durness Limestone. A further point of connection between the rocks of the two localities is the occurrence of white quartzite in association with the limestone at several places in Strath, and of representatives of the well-known "fucoid beds" at Ord, in Sleat. These latter strata form a persistent band between the base of the limestone and the top of the quartzite, which may be traced all the way from the extreme north of Sutherland southward into Skye. Palæontological evidence confirms and completes the proof that the limestone is of Lower Silurian age. The author has obtained from the limestone of Ben Suardal, near Broadford, a number of fossils which are specifically identical with those in the Durness Limestone, and so closely resemble them in lithological aspect that the whole might be believed to have come from the same crag. Among the fossils are species of Cyclonema, Murchisonia, Maclurea, Orthoceras, and Piloceras. The relations of the limestones containing these fossils to the other rocks were traced by the author. He showed that the Lias rests upon the Silurian limestone with a strong unconformability, and contains at its base a coarse breccia or conglomerate, chiefly composed of pieces of Silurian limestone, with fragments of chert and quartzite. The metamorphism for which Strath has been so long noted is confined to the Silurian limestone, and has been produced by the intrusion of large bosses of granophyre (Macculloch's "syenite") belonging to the younger, or Tertiary series of igneous rocks. After the reading of the paper some remarks were made by Mr. Etheridge, Dr. Hicks, Mr. Marr, Dr. Hinde, and Mr. Bauerman. In thanking the Fellows for the reception they had given to his paper, Dr. Geikie said that a preliminary sketch of the results of the recent work of the Geological Survey in the north-west of Scotland would, he hoped, be presented to the Society early next year.—On the discovery of Trilobites in the Upper Green (Cambrian) Slates of the Penrhyn Quarry, Bethesda, near Bangor, North Wales, by Dr. Henry Woodward, F.R.S.—On *Thecospondylus daviesi*, Seeley, with some remarks on the classification of the Dinosauria, by Prof. H. G. Seeley, F.R.S.

Entomological Society, December 7.—Dr. David Sharp, President, in the chair.—Mr. Jenner-Weir exhibited, and made remarks on, twelve specimens of *Cicadetta hæmatoides*, collected last summer in the New Forest by Mr. C. Gulliver.—Mr. McLachlan exhibited a specimen of *Pterostichus madidus*, F., which he had recently found in a potato. It seemed questionable whether the beetle had been bred in the cavity or had entered it for predaceous purposes. Mr. Theodore Wood, Mr. Kirby, and Mr. Herbert Cox took part in the discussion.—Mr. McLachlan also exhibited two specimens of a species of Trichoptera—*Neuronia clathrata*, Kol.—which occurred rarely in Burnt Wood, Staffordshire, and elsewhere in the Midlands. On inquiry he was informed that the two specimens exhibited had been found in the Tottenham Marshes.—Mr. Porritt exhibited a series of *Cidaria russata*, from Yorkshire, the Isle of Man, the Hebrides, and the south of England. The specimens from the two first-named localities were almost black.—Mr. Verrall exhibited a specimen of *Mycetæa hirta*, Marsh., which was found devouring a champagne-cork. The Rev. Canon Fowler remarked that certain *Cryptophagi* had the same habit. The discussion was continued by Mr. McLachlan, Mr. Jenner-Weir, and Dr. Sharp.—Canon Fowler exhibited specimens of *Acronycta alni* and *Leiocampa dictæa*, which came to the electric light on Lincoln Cathedral during the Jubilee illuminations. He also exhibited a specimen of *Harpalus melancholicus*, Dej.—Mr. Billups exhibited, for Mr. Bignell, an interesting collection of British oak-galls. He also exhibited the cocoon and pupa case of a South American moth, from which he had bred 140 specimens of a species of Ichneumonidæ.—Mr. O. Janson exhibited, for Mr. C. B. Mitford, a collection of Lepidoptera from Sierra Leone.—Mr. White exhibited a curious structure formed by white ants at Akyab.—Mr. Waterhouse exhibited a series of diagrams of the wings of insects, and read notes of observations on the homologies of the veins—a subject to which he had given especial attention for some time past. Mr. Champion, Mr. Verrall, Mr. McLachlan, Dr. Sharp, and Mr. Poulton took part in the discussion which ensued.—Mr. G. T. Baker contributed descriptions of new species of Lepidoptera from Algiers.—Mr. Gervase F. Mathew communicated a paper entitled "Life-histories of Rhopalocera from the Australian Region." The paper was accompanied by elaborate coloured drawings of the perfect insects, their larvæ and pupæ.—Mr. F. Merrifield read a report of progress in pedigree moth-breeding, with observations on incidental points. Mr. Francis Galton alluded to the close attention Mr. Merrifield had given to the subject, and complimented him on the neatness, ingenuity, and skill with which his experiments had been conducted, and on the results he had obtained therefrom. Mr. Poulton, Dr. Sharp, Prof. Meldola, and others continued the discussion.

Chemical Society, December 1.—Mr. William Crookes, F.R.S., President, in the chair.—The following papers were read:—The alleged existence of a second nitroethane, by W. R. Dunstan and T. S. Dymond.—An extension of Mendeléeff's theory of solution to the discussion of the electrical conductivity of aqueous solutions, by Holland Crompton.—Note on electrolytic conduction and on evidence of a change in the constitution of water, by Henry E. Armstrong.—Bismuth iodide and bismuth fluoride, by B. S. Gott and M. M. Pattison Muir.—The action of hydrogen sulphide on arsenic acid, by B. Branner, Ph.D., and F. Tomicek.—Note on the constitution of mairogallol, by C. S. S. Webster.

PARIS.

Academy of Sciences, December 12.—M. Janssen in the chair.—On the law of errors of observation, by M. J. Bertrand. Two propositions are affirmed: first, that, if a given magnitude be repeatedly measured, and the measures grouped by twos in haphazard order, by selecting in each group the greatest of the two errors committed the relation of the mean of the squares of these greatest errors to the mean of the squares of all the errors will converge towards the value $1 + \frac{2}{\pi}$, when the number of essays increases indefinitely; second, if the measures be similarly grouped in threes, the mean of the squares of the

greatest errors in each group divided by the mean of the squares of all the errors has for probable value $1 + \frac{2\sqrt{3}}{\pi}$, and approaches indefinitely towards this value according as the number of essays is increased.—Comparison of the various systems of electric synchronization for astronomical clocks, by M. C. Wolf. These remarks are made in reference to M. Cornu's recent communication on a new process of synchronizing time-pieces. The various systems hitherto employed for this purpose are passed in review, and their respective merits and defects are studied with exclusive reference to their suitability for employment for synchronizing time in observatories, towns, &c.—On the various modes of explosive decomposition of picric acid and the nitric compounds, by M. Berthelot. This inquiry, instituted in consequence of the doubts recently raised regarding the property of picric acid to explode by heating alone, throws much light on the various modes of decomposition of the nitric compounds properly so called, showing how these various modes depend on the initial temperature of the decomposition.—Remarks in connection with the presentation of a work entitled "Collection des anciens Alchimistes Grecs," by M. Berthelot. This "Collection," just issued by M. Berthelot with the co-operation of the Greek scholar, M. Ch. E. Ruelle, embodies much information regarding the origin of alchemy, the precursor of the modern science of chemistry. Compiled from unedited Greek manuscripts scattered over the public libraries of Europe, it comprises about 400 pages of Greek texts dating from the Alexandrine and Byzantine periods, and mostly anterior to the writers who stimulated chemical studies in the West. Amongst the treatises here for the first time edited are those of the pseudo-Democritus, of Synesius, and Olympiodorus, with French translation, copious notes and commentaries. In the introduction of 300 pages is embodied much information on the mystic relations of metals and planets, on the spheres of astrologists, on the old chemical signs and notations here reproduced by the photogravure process, the whole forming a sequel to the author's work "Sur les Origines de l'Alchimie," presented to the Academy two years ago.—On the application of photography to meteorology, by M. J. Janssen. These remarks are made in connection with the presentation of a series of large photographs which were taken on the Pic du Midi last October with a view to recording meteorological phenomena by the photographic process. The series comprises four views of the section of the Pyrenees within the horizon of the Peak at sunrise just before the solar rays have affected the almost continuous mass of clouds stretching from the Atlantic to the eastern part of the Pyrenees, filling all the valleys and enshrouding all but the highest summits of the range. Other photographs exhibit these clouds when acted on by the early rays of the luminary, and converted into the semblance of a storm-tossed sea. Images were also taken of the remarkable effects observed at sunset, and the satisfactory results of this first essay made it evident that photography may be applied with great advantage to the study of atmospheric phenomena.—Researches on the theory of the figure of the planets, by M. O. Callandreau. These researches, forming a second contribution to the study of the planets, are devoted more especially to the larger members of the solar system, in which the extent of flattening of the poles is an element which cannot be neglected in the general calculation.—On the compressibility of the solution of ethylamine in water, by M. F. Isambert. The experiments here described confirm the conclusions already arrived at by the author, showing that the aqueous solutions of the ammoniacal bases must be regarded as true chemical combinations, more or less dissociated, and dissolved in an excess of water.—On the geographical distribution of the Actiniæ inhabiting the French Mediterranean waters, by M. P. Fischer. A list is given of the thirty-three species already determined on the south coast of France. Of these sixteen are found also on the French Atlantic coast, which comprises twenty-four species not yet discovered in the Mediterranean. The northern limits of the French species have been clearly determined, but not so the southern, several forms occurring also in the Red Sea, and on the North and West African seaboards.

STOCKHOLM.

Royal Academy of Sciences, December 14.—Considerations on some theories of atmospheric electricity, by Prof. Edlund.—On the displacement of the shore line along the coasts of Sweden, by Dr. L. Holmström.—An account of the cosmological theory of Mr. Norman Lockyer, and of the views of Nordenskiöld on the subject, by Prof. Baron Nordenskiöld.—On post Glacial deposits containing *Ancylus fluviatilis*, by H. Munthe.—On *Rubus corylifolius*, Arrh., and *Rubus pruinosus*, Arrh., their nomenclature and value as species, by Dr. L. M. THE ROSICRUCIANS.

The Real History of the Rosicrucians. By Arthur Edward Waite. (London: George Redway, 1887.)

WE have since the receipt of this work for review endeavoured to ascertain what notions existed in the brains of our acquaintances on the subject of the Rosicrucians, and have posed the question "Who and what were they?" to many sorts and conditions of men. The minds of many were absolute blanks on this subject: some thought it was the name of a benefit society—some that it was a kind of freemasonry. One gentleman knew Rosicrucian as "the winner of the Alexandra Plate at Ascot in 1871," and but few had any intelligible notion on the matter. We do not estimate our neighbours at a much lower rate than the average; and it may therefore be granted that there is a large section of the British public to whom the Rosicrucians and their doings are unbroken ground, and that there is ample justification for the appearance of a book which is calculated to dispel the prevailing ignorance.

Mr. Waite has already made "the mysteries of magic" his theme, and consequently comes before us as no uncertain guide in the mazes of the occult. In his present work he furnishes a sketch of the state of mystical philosophy in Germany at the close of the sixteenth century, when the Reformation had removed their fetters from the inquirers. Of these there were many, for men's minds seethed with an infinity of speculations, as well philosophical as religious. The Neo-Platonic philosophy, which had lingered throughout the Middle Ages, once again came into more extended repute, and was professed by various disciples, until German mysticism culminated with Paracelsus. It was at such a period of complex opinions and of mystical ways of thought that the existence of the Rosicrucian fraternity was first revealed to the world. The manifestoes put forth by the brotherhood consisted of the "Fama Fraternitatis; or a Discovery of the Fraternity of the most Laudable Order of the Rosy Cross," and of the "Confessio Fraternitatis R.C. ad Eruditos Europæ." In the latter work are incorporated "thirty-seven reasons of their purpose and intention": these condemn the Pope and Mahomet; offer vast treasure to the head of the Roman Empire; disparage the moribund philosophy of the day, offering in its place the meditations of the brethren, who arrogate to themselves an acquaintance with what is transacted in the farthest regions of the earth. Great promises of a general reformation are made; the knowledge of Nature is eulogized beyond the transmutation of metals or the possession of the supreme elixir. The Society professes to accept the Bible as its oracle, whilst it sagely condemns the innumerable expounders who "make a sport of Scripture as if it were a tablet of wax." The brethren were apparently unsuccessful as linguists, for they are careful to explain that having the use of a magic writing and language they are not so eloquent in other tongues, "least of all in this Latin, which we know to be by no means in agreement with that of Adam and of Enoch."

In the "Fama Fraternitatis" we have an exposition of their religious views, a condemnation of "ungodly and accursed gold-making," an offer of communion to such as shall seek them in sincerity, and an account of their origin. They claim that their founder was brother C. R. C. (subsequently identified with Christian Rosencreutz), a noble German born in 1378. At five years of age he was placed in a cloister, "where he learned indifferently the Greek and Latin tongues," and started with one of the monks for Jerusalem. The monk died, and brother C. R. C. never reached his destination; but his skill in physic obtained for him the favour of the Turks, and becoming acquainted with the wise men of "Damcar," in Arabia, he came thither at the age of sixteen. The unfortunate fact that "Damcar" is unknown to chorographers prevents our gratifying our readers by identifying its locality. Here he was received by the learned as one long expected, and was initiated into their arcane wisdom. Thus primed, he came, three years later, to Egypt, and thence to Fez, where he acquired cognizance of the elementary inhabitants, who revealed unto him many of their secrets. After two years he set sail for Spain to confer with the learned, generously offering to correct their errors in moral philosophy and in the arts, as well as the abuses obtaining in matters ecclesiastical. His proposals were, for some unaccountable reason, slighted by the Spanish *savants*, and the misprized brother returned to Germany, gathered round him a few disciples, founded the fraternity of the Rosy Cross, and died at the ripe age of one hundred and six. His tomb was after the lapse of one hundred and twenty years discovered, together with many mystical adjuncts, in a concealed vault. His fair and worthy body was found whole and unconsumed, and resting in proximity to the *Vocabularium*, *Itinerarium*, and Life of Paracelsus. From the "Fama" we learn that the brotherhood acknowledged the divinity of Jesus, the resurrection, a personal devil, two sacraments, the Bible as "the whole sum" of their laws, and the Pope as Antichrist. Such were their religious beliefs. In philosophy they sought a universal synthesis; they aimed at the substance at the base of all the vulgar metals; they held, although they did not originate, the doctrine that self-propagating elemental beings people earth, air, fire, and water, and believed in the *signatura rerum*, a "certain organic vital activity," which is frequently expressed in the exterior form of things, indicating their interior qualities. They seem to have used some form of practical magic, and accepted as fact the transmutation of metals and the existence of "the supreme medicine of the world." With such a nostrum in their possession the least they could do was to heal the sick, and they were accordingly charged to do so gratuitously. The whole manifesto concludes with a declaration that, although making no mention either of their names or meetings, everyone's opinion should come to their hands, in what language soever it be, and that none giving their names should fail to receive a personal visit or a written communication.

Unfortunately, the assertions contained in the publications of the brotherhood are, as Mr. Waite shows, confuted by a critical examination. We are asked to accept the fabulous oriental city, the youth of brother R. C., in spite of his precocious skill in physic, and his erection of a House of the Holy Spirit, where an "unspeakable concourse of

the sick" thronged for cure notwithstanding the fact that the Society remained unknown to Europe till the beginning of the seventeenth century. Thus much we might even be induced to swallow on the *credo quia impossibile est* principle; but the finding, in 1494, of the works of Paracelsus, who had been born in the previous year at Einsiedeln, staggers our faith. Courtesy forbids the lie direct, but, to use a phrase of Mr. Newell's, we incline to think that if the author of the "Fama" ever wrote a work of fiction it would sell.

We have, then, to seek elsewhere for an explanation of the Society's inception, and must do so in post-Lutheran times; the violence of its anti-Papal prejudices, and its ultra-Protestant principles, prohibiting the attribution of its origin to a more remote period. It will render the comprehension of the case more easy if, before theorizing as to the foundation of the Rosicrucians, we note the varying opinions which have obtained as to the signification of the letters F.R.C., which formed the title of the brotherhood, and as to the badge which they employed.

Michael Maier conceived that R. signified Pegasus, and C. *lilium;* others that R. was *ros*, dew, and C. *crux*, cross, dew being deemed the most powerful dissolvent of gold, and the cross being in chemical language equivalent to light—the menstruum of the red dragon, the producer of gold—since the letters L V X are all formed by the limbs of the cross. Again, it has been imagined that F.R.C. stood for Fratres Roris Cocti, or dew digested for the work of transmutation. The Society's published documents, however, sanction the generally received opinion that R. is for *rosa*, rose, and C. for *crux*, cross, and that the letters F.R.C. are the initials of Fratres Rosatæ Crucis.

The device of the Society is a red rose on a red or golden cross, this being usually placed on a calvary. Mr. Waite has some interesting memoranda upon the occult significance of the rose as the feminine emblem contrasting with the masculine cross; of the Brahmanic rose, the residence of the Deity, recurring with similar significance in Dante's Paradise; of Buddha and Indra crucified for stealing the blossom; of the identification of Jesus with the crucified flower; of the rose of Bacchus which enabled Midas to turn all things to gold; of that of Harpocrates consecrated to silence; and so forth. He cites the author of the "Summum Bonum," who sees in the symbol "the cross sprinkled with the rosy blood of Christ"; and the Abbé Constant, who has identified the rose with scientific initiation and the cross with religion, and beholds in their conjunction that happy union the antithesis of which has been chronicled by Mr. Draper. He is nevertheless fain to confess that the whole question of the significance of the crucified rose in its connection with the Society is one of pure conjecture, and that no presumption is offered by the fact of its adoption for its connection with universal symbolism.

Mr. Waite divides the Rosicrucian theorists into three categories. Firstly, such as accept the history of Christian Rosencreutz as that of an actual personage and the "Fama Fraternitatis" as a true history. These he regards as impervious to argument. Accepting the dictum of De Quincey, that the "Fama" is "monstrous and betrays itself in every circumstance," he decides that the legend of Christian Rosencreutz is not historically true, and that the Society did not originate as described. In the second section he places those who regard both personage and relation as mythical; and, in the third, believers in the existence of the secret Society, but who reject the "Fama" as a fiction.

The theorists of these latter categories have mostly sought the author of the Rosicrucian manifestoes amongst the *literati* of the period, whether they regarded him as a hoaxer or a satirist or as the spokesman of a hidden brotherhood. By them the publications in question have been variously attributed to Taulerus, Luther, Wiegel, Joachim Junge, Ægidius Gutmann, or Johann Valentin Andreas. Mr. Waite considers that it is only in the case of the last named that there is any sufficient evidence to support the plea of authorship. The grounds upon which that plea rests are, amongst others, that the writings of Andreas show him to have uniformly favoured secret Societies as a means for the reformation of his age and country. He is the acknowledged author of a work entitled the "Chymical Marriage of Christian Rosencreutz"—a species of alchymical "Pilgrim's Progress," which, after remaining several years in manuscript, was printed at Strasburg in 1616, and a translation of which occupies 97 pages of the present volume. The first manifestoes of the Society had only borne the initials C. R. C.; but the issue of 1615 calls it the Bruderschafft des Rosen-Creutzes, and it is hence argued that the manifestoes and the "Chymical Marriage" had a common author. The hero of the latter work binds a blood-red ribbon cross-wise over his white linen coat, and sticks four roses in his hat—a noteworthy coincidence, the arms of the Andreas family being a saltier between four roses. The connection of this escutcheon with the device of the crucified rose has been urged, as also the identity of the acknowledged principles of Johann Valentin with those set forth in the manifestoes, in favour of his authorship. This opinion has gained support from certain utterances of Prof. Besoldt, himself an intimate friend of Andreas. Against this view it must be remembered that Andreas describes the "Chymical Marriage" as a *ludibrium* of his youth, though he must have been aware that its alchymical contents would certainly be accepted seriously when published in his maturer years; and it is submitted that he, a man of known intellectual nobility, could scarcely have perpetrated a hoax the reprehensible nature of which he had himself stigmatized when dealing with the Rosicrucian manifestoes. Again, the accepted symbol of the fraternity was never a saltier between four roses, but either a Latin cross with a rose at the point of intersection or a cross rising out of a rose. The identification of the arms of Andreas with a badge of the brotherhood, which forms one of the strongest arguments in favour of his authorship, thus falls to the ground. These and other arguments elaborated by Mr. Waite suffice to render it very uncertain that the Rosicrucian publications emanated from Andreas. Mr. Waite suggests that Andreas may have been associated with the previously existing Militia Crucifera Evangelica, and, when disgusted with its assumption of occultism, have attempted to replace it by a practical Christian association free from mysticism and its symbols, from pretension to arcane endowments or transcendent powers. But he admits that undoubted difficulties beset this theory, and adds: "To my own mind it is far from satisfactory, and, from a careful consideration of all available materials,

I consider that no definite conclusion can be arrived at." He further declares that the esoteric form of the Society's symbol was a rose in the centre of which is figured a Latin cross: he calls attention to the seal of Luther, on which a heart, surmounted by a cross, is inclosed by the outline of a rose, and hence gathers that the unknown founders of the Society chose this emblem, not from any recondite associations, but simply because the reforming monk was their idol.

With the case of Johann Valentin Andreas the interest of the work culminates. When we have learnt that nothing can be determined, and that there is every reason to believe that could we probe the heart of the mystery we should find little to reward our search, we care little for a record of the progress of Rosicrucianism in France and Germany, or for the writings and biographies of Rosicrucian apologists such as Michael Maier, Robert Fludd, Thomas Vaughan, and John Heydon. Artistically, this continuation is an anti-climax, and the chapters which compose it might have been fittingly relegated to the appendix, together with those remaining sections which are devoted to a refutation of the claims of the Freemasons and of modern Rosicrucian Societies to connection with the original fraternity of the Rosy Cross.

The claim which Mr. Waite puts forward to be considered an impartial historian we readily admit, for we have rarely seen a work of this description that was so free from all attempts at the distortion of facts to dovetail with a preconceived theory. His style is perspicuous, and contrasts most favourably with that of his Rosicrucian rival, Mr. Hargrave Jennings, against whom he tilts with much vigour throughout his pages.

The most interesting portions of the book are those where the author is willing to speak himself; for the lucubrations of the *illuminati*, which fill some 250 out of the 446 pages composing the work, are for the most part insipid and fatuous to the lay mind. It was doubtless necessary to include transcripts of the "Fama" and the "Confessio," these being the authoritative expositions of the Society's views, but we could have spared much of the "Chymical Marriage," and all of the "Universal Reformation of the Whole World by order of god Apollo," which Mr. Waite describes as a fairly literal translation of advertisement 77 of Boccalini's "Ragguagli di Parnasso, Centuria Prima," and which, he adds, "throws no light upon the history or claims of the Rosicrucians." Neither is much learnt from the speculations of the apologists, whose philosophy, although mysterious, is not to be readily identified with that of the fraternity as officially set forth. In wading through such documents, one is reminded of Mr. Shandy's exclamation when Rubenius has furnished him with information on every conceivable point except upon the one on which he sought for it. The work on the whole is well done and satisfactorily produced, but it lacks an index. Had the author furnished as good an index to his volume as the enterprising publisher, Mr. Redway, has added to his advertisements, he would have enhanced its value as a book of reference. To those students of occultism whose palates, undebauched by the intellectual *hashish* of the rhapsodies of mysticism and the jargon of the Kabala, can still appreciate a plain historical statement of facts we gladly commend the book.

THE MECHANICS OF MACHINERY.

The Mechanics of Machinery. By Alex. B. W. Kennedy, Professor of Engineering and Mechanical Technology in University College, London. (London: Macmillan and Co., 1886.)

ALTHOUGH the author explains in his preface that this work is destined to meet the requirements of young students of engineering, still the mathematical student of mechanics would reap immense benefit from a careful study of the novel treatment presented here, and would recognize the shortcomings and unsatisfactoriness of the treatises usually put into his hands.

Here we have a treatise on *real* mechanics, with diagrams, drawn accurately to scale, of *real* machines, and illustrative examples drawn from *real* life, while the ordinary mathematical treatise put into the student's hands is generally a great contrast, by reason of its abstract method of treatment, the unpractical nature of the problems discussed, and its diagrams resembling nothing that ever existed, purposely drawn badly, for the reason, it is urged, that a bad draughtsman can copy them more easily.

Prof. Kennedy, in his preface, explains how he has been driven to the vernacular use of the word "pound" as a name for a unit both of weight and of force, as "the adoption of any other plan would have made the book practically useless to almost all engineers so long as the thousand-and-one problems of their every-day work come to them in their present form." This plan is so perfectly clear and intelligible to ordinary practical men to whom dynamical problems on a large scale are a reality and not a mere theoretical abstraction that it is a pity that Prof. Kennedy has gone back on his principles in inserting in § 30, on force, mass, and weight, an attempt at explanation of the confusion of ideas in books on mechanics written by mathematicians, due to the introduction of the word "mass," a word which the engineer never requires.

The explanation of the relation between force, weight, and acceleration is so simple that it may very well be given here. Taking the gravitation unit of force, universally employed by our engineers, as the attraction of the earth on a weight of one pound, and calling this the *force* of one pound, then a force of f pounds acting on a weight of w pounds will produce acceleration a, such that $\frac{f}{w} = \frac{a}{g}$, by Newton's Second Law of Motion; or, $f = \frac{wa}{g}$.

But, if v is the velocity acquired in feet per second, and s the number of feet described in t seconds from rest, then it is shown in Chap. VII. of the present treatise that $v = at$, $\frac{1}{2}v^2 = as$; so that $ft = \frac{wv}{g}$, and $fs = \frac{wv^2}{2g}$.

Here fs represents the work done on the body in foot-pounds of work, and the dynamical equivalent is $\frac{wv^2}{2g}$ foot-pounds of kinetic energy.

So also the product ft is called the *impulse*, in *second-pounds*, of the force f acting for the time t, and its dynamical equivalent is $\frac{wv}{g}$ units of momentum, the momentum of w pounds moving with velocity v being defined by the product wv.

Now the mathematician noticed that in these equations the quantity w occurs divided by g, so he said, Let us call the quotient $\frac{w}{g}$ the "mass" of the body, and denote it by the letter m, so that $w = mg$, equivalent to taking g pounds as the unit of mass.

Unfortunately, in this way the "mass" of a body, which is the measure of an unalterable quantity, is now measured by a variable unit, while the "weight" of a body, which is now defined by the mathematician as the force with which the earth attracts the body, depending on the local value of g, is, although a variable quantity, always represented by the same number—namely, the number of pounds in the body.

This confusion is entirely obviated if, following the engineers, we discard the word "mass" altogether; if we measure, as is customary in ordinary life, weight in pounds, and if we change the unit of force to the absolute unit, called by Prof. James Thomson the "poundal." Now, if a force of p poundals acts on a weight of w pounds, it will produce acceleration a, such that $p = wa$, and then $pt = wv$, and $ps = \frac{1}{2}wv^2$, so that ps, the work done in foot-poundals, has the dynamical equivalent $\frac{1}{2}wv^2$ foot-poundals of energy; not, as the footnote to p. 248 would imply, that $\frac{1}{2}mv^2 = \frac{wv^2}{2g}$, because $m = \frac{w}{g}$, but because $\frac{1}{2}mv^2$ is the kinetic energy in foot-poundals of m pounds moving with velocity v; while the impulse pt second-poundals, has the dynamical equivalent of wv units of momentum.

The unit of momentum has not yet received a name, but the Committee on Dynamics of the Association for the Improvement of Geometrical Teaching is preparing to suggest a distinctive name.

Supposing then that w represents the weight of a body in pounds, how is it possible, as asserted on pp. 219, 220, that $\frac{w}{g}$ remains constant when the body is moved about to parts of the earth where g has different values? and where is the practical value of estimating the effective inertia in terms of the variable unit of mass, as in § 48, when the constant unit of weight would be simpler and practically more intelligible?

These theoretical questions of units of force and weight have been discussed here at some length, as it is important that Prof. Kennedy in his next edition should carefully revise this part of the subject, which will best be done if he disregards the discussions on "mass" of the ordinary text-books, and if he writes always in the ordinary vernacular language used by engineers.

In Chapter XII., on "Friction in Machines," the true laws of friction are given for the first time in any treatise in this country, Morin's illusory laws as usually taught being entirely discarded. With proper lubrication of machinery the question of friction is properly a question of viscous liquid motion. Some interesting applications, with graphical solutions to such problems as friction-brakes and pulley-tackle, are appended, which ought immediately to be incorporated into academical text-books. Of the same nature are the problems on train-resistance in Chapter IX.: a slip on p. 328 of introducing an extraneous factor, π, need only be mentioned here, as the author himself has already corrected it.

We have discussed the dynamical part of the book first, but it is the kinematical part, which treats of mechanism, which forms the greater half of the book. Here the author has analyzed the classification of machines and their elementary parts with great skill and clearness, and illustrated the theory with excellent diagrams. The idea of the "centrode" is largely used in the book, the invention of which is originally due to Belanger. While analyzing fully the centrodes of valve mechanism, the author has mysteriously stopped short of the discussion of valve diagrams, which, in the steam-engine, is the most important practical application of kinematics. Peaucellier's parallel motion is fully described, with Kempe's amplifications: it would be instructive to see a diagram of Peaucellier's motion as applied to an actual steam-engine. Pröll's velocity and acceleration diagrams are carefully explained, with extensions due to the author: this subject has received considerable development of late from German writers, and is capable of solving very elegantly such difficult and important practical problems as, for example, the determination of the bending moment at any point of a connecting rod.

A very useful table of moments of inertia concludes the volume, but here we should prefer to see k the radius of gyration, called in this book the radius of inertia, or rather k^2, the square of the radius, tabulated, side by side of the corresponding area A or volume V.

In conclusion, Prof. Kennedy's students are to be congratulated on the possession of such an admirable textbook, and it is to be hoped that the style and influence of its teaching will make itself widely felt outside of professional circles.

A. G. GREENHILL.

THE SOLOMON ISLANDS.

The Solomon Islands and their Natives. By H. B. Guppy, M.B., F.G.S., late Surgeon R.N. (London: Swan Sonnenschein, Lowrey, and Co., 1887.)

THE Solomon Islands, whether we consider the romantic narratives of their discovery and rediscovery, the comparatively unsophisticated character of their inhabitants, their faunistic and floral relationships, or their remarkable geological structure, are of more than common interest to the scientific world, and it is a matter for congratulation that their description has been undertaken by a traveller and historian so eminently qualified for the task as is Dr. Guppy. The book which he has produced is a rich storehouse of interesting and important observations, and will henceforth be an indispensable work of reference to every student of the races inhabiting the Pacific islands. It is worth while to lay stress upon this fact for the sake of encouraging future travellers to give their observations to the world, because Dr. Guppy did not at first intend to make any special investigation of the habits and manners of the inhabitants, but was led to do so by the want of interest displayed by those who seemed to have so much better opportunities.

The Solomon Islanders seem to be of various types in different parts of the group, but their prevailing characters are distinctly Melanesian or Papuan. A circumstance is pointed out which seems to indicate the Indian Archipelago as having been the route by which the Eastern Polynesians reached the Pacific. This circumstance

consists in the possibility of tracing the native names of certain trees across the Central Pacific from the Indian Archipelago to the Austral and Society Islands. For instance, in the former locality the *Barringtonia speciosa* goes by the names of *Boewa boeton* and *Poetoen;* in the islands of the Bougainville Straits in the Solomon Group it is called *Puputu;* in Fiji, *Vutu;* in Tonga, *Futu;* and in the Hervey and Society Islands, *E-Hoodu* or *Utu*. The name thus appears to have undergone a kind of progressive modification as the tree has receded from its original home. The large amount of information which Dr. Guppy has been able to collect is mainly due to his remarkable tact in dealing with the natives: he seems to have at once succeeded in establishing friendly relations with all those with whom he came in contact, and though he was continually in their power, going long journeys with no other escort than a body of them, he met with nothing but kindness at their hands. He modestly ascribes this satisfactory result mainly to the soothing influences of tobacco, without which, he says, the white traveller in these islands "is worse off than a man without any money in his purse in London," but something must undoubtedly be attributed to the kindly and conciliatory personal influence of the writer himself.

Where so much excellent matter is given it seems ungrateful to ask for more, but it is impossible to repress the desire for knowledge regarding the dwellers in the interior of these islands, who seem to be always at war with the coast tribes, and are regarded by them with so much contempt that "man-bush" is with the latter a common term of reproach. Very interesting, too, are the worked flints, not unfrequently found in the soil either during agricultural operations or after heavy rains. They may probably have been the work of the primitive Negrito race which was at one time widely spread over this region of the globe. It is worthy of notice that in none of the islands visited by the author was any chalk found which contained flints, but there are records of its existence in Ulaua, another member of the group.

Two chapters, certainly not inferior to the rest of the work in interest, are occupied by a history of our knowledge of this group of islands. It does not often happen that one who has distinguished himself as an explorer is willing to undertake a piece of literary work, calling for the patient and critical examination of an old manuscript, but it is a peculiarly happy chance that has thrown the translation of Gallego's journal into the hands of one whose exceptionally accurate knowledge of the locality has no doubt enabled him to avoid errors into which the best of scholars without such information must have fallen. Hernando Gallego was chief pilot to an expedition which was despatched from Peru under the command of Alvaro de Mendana for the ostensible purpose of spreading the Christian faith among the islanders of the Pacific. In the year 1567 they reached the Solomon Islands and gave names to most of them, but lest the English should attempt to possess themselves of the newfound territory no account of the discovery was published; and hence, after one or two futile attempts on the part of the Spaniards to refind and colonize them, knowledge of their whereabouts gradually became a vague tradition, and at length even their very existence was doubted. Two hundred years elapsed before Carteret sighted and anchored off the group, but he did not land. Then in rapid succession came the discoveries of Bougainville, Surville, Maurelle, and Shortland, but none of these identified their discoveries with the previous work of the Spaniards, and it was reserved for the genius of Buache to point out "that, between the extreme point of New Guinea as fixed by Bougainville and the position of Santa Cruz as determined by Carteret, there was a space of 12½° longitude, in which the Islands of Solomon ought to be found." His conclusion, that the islands seen by Carteret and others were the same as those previously discovered by the Spaniards, though long disputed, is now generally admitted, and justice has been rendered both to the gallant explorers and to the laborious and gifted investigator.

In reading this journal it is impossible not to wish that the chart accompanying the volume were on a somewhat larger scale, that more names had been inserted, and that the author, even if he did not feel at liberty to restore those given by the original discoverers, had at all events inserted them within parentheses.

Of Dr. Guppy's work in natural history it would be difficult to speak too highly. It embraces, in addition to a mass of anthropological material, to which reference has been made above, a general account of the chief divisions both of the animal and vegetable kingdoms. Special attention may be called to the observations upon floating seeds and seed-vessels, which have been utilized by Mr. Botting Hemsley in his work on the oceanic dispersal of plants, and to a remarkable fungous growth (*Pachyma?*) found lying loose upon the soil. Of reptiles, batrachians, and mollusca many new species were obtained; an interesting discussion is given regarding the origin of the edible birds'-nests, and an account of attempts to ascertain by direct evidence whether the *Birgus latro* is really able to husk and break cocoa-nuts for itself, as well as details of experiments on the power of various animals to resist submersion in sea-water. The Solomon Islands stand in a remarkable zoo-geographical position, on the boundary between the Polynesian and Indo-Malayan regions, hence a special interest attaches to these lists of species and biological data. The size of the author's collections is little short of marvellous when it is remembered that for two out of the three years spent there his own cabin was the only place where he could store them. He seems, indeed, to have met with but scanty encouragement from those quarters whence he might reasonably have expected it, and every Briton should blush when he reads and reflects upon the truth of the closing words of Dr. Guppy's Introduction :—

"Stifling my own patriotic regrets, I cannot but think that the presence of Germany in these regions will be fraught with great advantage to the world of science. When we recall our spasmodic efforts to explore New Guinea and the comparatively small results obtained, when we remember to how great an extent such attempts have been supported by private enterprise and how little they have been due to government or even to semi-official aid, we have reason to be glad that the exploration of these regions will be conducted with that thoroughness which can only be obtained when, as in the case of Germany, geographical enterprises become the business of the State."

CROWN FORESTS AT THE CAPE OF GOOD HOPE.

Management of Crown Forests at the Cape of Good Hope under the Old Régime and under the New. By John Croumbie Brown, LL.D. (Edinburgh: Oliver and Boyd; London: Simpkin Marshall and Co., 1887.)

IN June last we noticed a work by Dr. Brown dealing with the schools of forestry in Germany, which, it appears, was the author's fifteenth volume on a variety of forest subjects. He has now presented the public with a new volume, out of a store of thirty said to be ready for publication. This plethora of forest literature showered upon us by Dr. Brown is becoming alarming. We pointed out on the previous occasion that the English reader has, in reality, very little interest to spare for forest questions, and what little does exist will certainly not be augmented by literature of the class under review. Here we have a goodly volume, comprising 352 pages of print, made up of a motley collection of old and new official reports, proceedings of an endless succession of Committees, &c., which, even if it were an official Blue-book, would have to be pronounced badly arranged and filled with quantities of irrelevant matter. We do not mean to say that there is not a silver thread running through the whole; what we desire to point out is that the information to be conveyed and the lesson to be learnt could with the greatest ease have been arranged in a pamphlet of thirty or forty pages. To scatter a few grains amongst a huge quantity of chaff is highly objectionable, and it is our duty to protest in the strongest terms against this class of book manufacture. The author had a really interesting story to tell, which, if placed before the public in a small pamphlet or an article in a periodical, would have been sure to attract attention, and might have done some good.

The story to which we refer is peculiarly English. It has been said that whenever we engage in war we generally begin by incurring some reverses: we then gather up our strength, and meet the enemy in such force that the strife is certain to end in success. If this holds good as regards our frequently occurring little wars, it seems to be no less applicable to our Civil administration. Looking, for instance, at our forest policy at the Cape, which Dr. Brown has brought before us in the present volume, it will be seen that after prolonged playing with the question, and after the forests had been well-nigh ruined, vigorous steps were taken to redeem the past.

As in most countries, the forests at the Cape were originally made use of by the population without let or hindrance. Then, with the arrival of European administration, came the colonist, who also betook himself to the woods, partly to clear the land for cultivation, partly to supply himself with material for his domestic requirements, and partly to cut and sell timber for the purpose of making a livelihood. The woodlands, which appeared sufficient to supply the wants of the native population, were soon found to be incapable of bearing the additional strain caused by a European Government and the inroads made by the accompanying colonist. Some enlightened person perceived that the forests could not last at the new rate of consumption of its produce, and raised the alarm. Inquiries were set on foot, officers reported, and Committees deliberated. It was found that the denudation of extensive areas had become an accomplished fact, and that more were rapidly following in the same path. The principal causes were, as in all similar cases, the following:—

(1) Reckless working of the forests by natives and colonists.

(2) Extensive and frequent fires overrunning the forests, destroying all humus, seedlings, and young trees, and damaging more or less the trees of more advanced age.

(3) Uncontrolled clearing of land for cultivation.

So much having been ascertained, the Government should at once have proceeded to take steps to counteract the evil; but only half-measures were adopted. The Government attempted to bring the forests under control by prohibiting certain acts, without providing an efficient agency to see the restrictions enforced. If in any instance they were enforced, it was found that they interfered with previously prevailing practices, complaints were made, and the strife swayed to and fro. Then the Government of the time tried various means to satisfy all parties. Once it resolved to throw the forests open to private enterprise by offering them for sale. In this manner a certain area passed into the hands of private parties, but fortunately only a limited number of lots were sold. Next, the forests were closed, but this also would not meet the case, and they were opened again, so-called licenses for the removal of fixed quantities of material being issued against small payments. There being no proper staff to control the operations, matters grew from bad to worse. About this time Dr. Brown appeared upon the scene, having accepted the appointment of Government Botanist of the Cape Colony in the year 1863. He soon perceived the unsatisfactory condition of the Cape woodlands, and he strongly urged the introduction of a more systematic treatment. Fresh inquiries were set on foot, new Committees sat and deliberated, but it was not until the year 1881 that really efficient measures were adopted. By that time the mischief had been done, and the yield of the forests was so low that, out of a total consumption of two and a quarter million cubic feet of timber, only a quarter of a million cubic feet came from the colonial forests, while a little over two million cubic feet were imported.

In the year 1881 the services of a French forest officer, Count de Vasselot de Regne, who had previously done excellent service in the fixing of the dunes and creation of extensive new forests at Royan, near Bordeaux, were secured as Superintendent of the Cape forests, and with his advent a new *régime* commenced. The selection of this gentleman, due, we believe, to Colonel Pearson, lately in charge of the English forest students at Nancy, was most fortunate. Although we are not acquainted with the Cape from personal experience, we have no hesitation in saying that the reports issued during the last six years prove the administration of the Cape forests to rest in very able hands, and that substantial progress has been made during that short period towards placing the management on a sound and solid basis. A fairly adequate and competent staff has been brought together, the forests are being demarcated, waste is being put down, fir conservancy has been begun, blank areas are being planted, and there is altogether a fair prospect that, after

some time, the colony will once more be in a position to supply the necessary forest produce from its own woodlands. At the same time the financial aspect of the business has not been overlooked, and there are indications that the woodlands will before long prove to be a source of substantial income to the colonial Exchequer.

The forests of the Cape deserve to be carefully preserved, not only for the purpose of their direct utility in providing timber and other produce, but also for their usefulness in other respects. Whether their existence will increase the rainfall to any appreciable extent may be a matter of doubt, but they certainly moderate the temperature and reduce evaporation; in other words, they husband the water which falls on the soil. This effect is all the more important, because Cape Colony is situated, approximately, between the 28th and 35th degrees of south latitude, and the rainfall over about half the area amounts to less than 10 inches a year, while only a comparatively small portion enjoys a rainfall of over 20 inches.

Considering these matters, we trust that the colonial authorities will now persevere in making up for past remissness by maintaining steadily a policy of efficient forest conservancy. It needed many warnings before the proper steps were taken, and in this respect no one deserves more praise than Dr. Brown. By raising his voice loudly during the years 1863-66 he has certainly deserved well of the Cape Colony. While it is a pleasure to record this, it is to be regretted that our author has not succeeded in placing the history of the case before the public in a more readable form than that adopted in the present volume. SW.

OUR BOOK SHELF.

Thomas A. Edison and Samuel F. B. Morse. By Van Buren Denslow, LL.D., and Jane Marsh Parker. (London: Cassell and Co., 1887.)

THIS book is an evident compilation, principally of newspaper cuttings from the other side of the Atlantic. The authors are Americans. Edison is posed as the inventor of the duplex and quadruplex systems of telegraphy, though each was invented in Europe when he was seven years old; while Morse is lauded as having sent the first telegram in 1844, when telegraphy was seven years old, and flourishing well in England. Edison's grandfather lived to be 102 years old, his father is now living at 83. It is to be hoped that he will live long enough to tire out these foolish defamers of his true merit, for merit, industry, and inventive skill he certainly has. Personally he is a charming man, and impresses one with his modesty and communicativeness. The phonograph, carbon transmitter, and glow lamp are quite sufficient to establish his fame without dragging in apparatus he simply altered or perhaps improved. We read in this silly book, "The very words 'electric light,' must stand for ever as closely associated with the name of Edison as is gravitation with Newton or the telescope with Galileo."

We read (p. 96):—"There have been four eras in the history of the magnetic telegraph. In each of these eras a citizen of the United States has been conspicuous. . . . The first era was that of Franklin and his kite. . . . The second era was that of invention—the era of Morse, Henry House (*sic*), and *Daniell* [so the authors reckon Daniell an American !]. Had the Daniell battery been known in 1827, one Harrison Gray Dyer, of New York, would have given to the world what Prof. Morse did not complete until some seventeen years after.

"The third era was that of the evolution of the telegraph —the multiplication of its effects. Of the many names conspicuous in this era none are more deserving of special mention than Hiram Sibley, and none take precedence of Thomas Alva Edison." [N.B.—Edison was born in 1847.] The fourth era was "an era of chaos in its beginning, when Morse lines, Bain lines, House lines, and O'Reilly lines, with their endless litigations over infringements of patents and broken contracts, local jealousies, disastrous competitions, unequal and capricious tariffs, made investing in telegraph stocks a sure method of throwing away money."

And this is history!

The following story is gravely told:—

"When the boy (Edison) was a little under six years old, he became greatly interested in the fidelity with which an old goose was brooding her nest of eggs. When the young family of golden-green goslings came out and took to the water, he was told that this astounding result was produced simply by the animal heat of the old bird sitting on them. The first lesson in organic chemistry was of a kind too remarkable to be let slip without testing it by experiment. Soon after the boy was missed. Messengers were sent after him everywhere, but he could not be found. 'By and by,' says the sister, 'don't you think father found him curled up in a nest he had made in the barn, sitting on goose eggs and hen eggs and trying to hatch them?'"

Sound, Light, and Heat. By Mark R. Wright. (London: Longmans, Green, and Co., 1887.)

WE gladly welcome the appearance of such an admirable text-book as the one before us. It embraces the work required for the various elementary examinations in sound, light, and heat, but it is in no sense a cram-book. The subjects are treated experimentally, and the arrangement is apparently that which practical experience in teaching has led the author to believe to be the best. The experiments described are thoroughly practical, but, at the same time, the apparatus required is comparatively simple. The author is of opinion—and we quite agree with him—that a beginner's time is best spent in making himself acquainted with the facts of science; he has accordingly given little space to theoretical considerations, but he has carefully avoided making statements that might lead the student to form notions at variance with the modern theories.

The drawings, and the descriptions of the apparatus they represent, leave nothing to be desired. The numerical examples, of which there is a great number, combined with the experimental treatment, entitle the book to rank as one of our best text-books of elementary science, and we can confidently recommend it.

Through the West Indies. By Mrs. Granville Layard. (London: Sampson Low, 1887.)

THE author of this little book spent several months in the West Indies, and heartily enjoyed her expedition. She has nothing very new to say about the various places she visited, but she writes pleasantly, and succeeds in conveying a vivid impression of many of the scenes by which she herself was strongly impressed. Occasionally she offers shrewd suggestions as to the industry and trade of the West Indian Islands, and she gives as an appendix a useful paper on "The Sugar Question." This paper contains the substance of notes and suggestions furnished by the Hon. W. H. Ioner, Member of the Legislative Council, Barbados.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

"The Conspiracy of Silence."

WILL you allow me a word on "The Great Lesson" by the Duke of Argyll? It is especially what is said about Darwin's coral-island theory in the following lines, to which I wish to refer:—"All the acclamations with which it was received were as the shouts of an ignorant mob. It is well to know that the *plébiscites* of science may be as dangerous and as hollow as those of politics. The overthrow of Darwin's speculation is only beginning to be known. . . . Reluctantly, almost sulkily, and with a grudging silence as far as public discussion is concerned, the ugly possibility has been contemplated as too disagreeable to be much talked about."

The terms "ignorant mob," "sulkily," and "grudging silence," as used above, cannot readily be forgotten if forgiven by men of science on this side of the Atlantic any more than by their brethren in England.

I am unable to see anything sulky or silent in the exposition of Mr. Murray's coral-island theory of over three pages in length, which was published and sent to all the scientific world in NATURE, vol. xxii. p. 351; nor in the many articles in the current literature and recent geological text-books that have since appeared. In this country no large text-book of geology has been issued since 1880; but Mr. John Murray's work has been fairly discussed, and, so far as I know, has always been recognized. Here at Williams College, for example, the views of Mr. Murray referred to have been expounded each year in the course in geology since 1880. One may, I take it, differ from the Duke of Argyll in accepting or rejecting, wholly or in part, any theory, without laying himself open to the charges quoted above. Of anything like sulkiness or grudging silence I have yet to see or hear the first evidence. There is indeed a "great lesson" in the article by the Duke of Argyll, but it is hardly the one he intended to give. SAMUEL F. CLARKE.

Williams College, Williamstown, Mass., December 5.

"DARWIN'S LIFE AND LETTERS" are now public property, and as reference to vol. iii. p. 242, shows—what nearly every scientific man knew—that the late Sir Wyville Thomson was distinctly anti-Darwinian in his views, it follows that the Duke of Argyll's inferences as to his reasons for urging Mr. Murray's withdrawal of the "new coral-reef theory" paper from the Royal Society of Edinburgh is illogical, not to say absurd. In justice to Sir Wyville's memory and in support of Mr. Bonney's surmise (NATURE, November 24, p. 77) I wish to state that, talking with Sir Wyville about "Murray's new theory," I asked what objection he had to its being brought before the public? The answer simply was: he considered that the grounds of the theory had not as yet been sufficiently investigated or sufficiently corroborated, and that therefore any immature, dogmatic publication of it would do less than little service either to science or to the author of the paper.

AN OLD PUPIL OF WYVILLE THOMSON'S.

December 17.

Greenland Glaciers.

I HAVE received a letter from Prof. Steenstrup, of Copenhagen, which gives further interesting information respecting the extraordinarily rapid advance of the Greenland glaciers, and corroborates the opinion I expressed in the paper I recently read before the Geological Society, that the rate of advance during the Glacial period may have been far more rapid than that generally assumed, and that that period should be much shortened. Prof. Steenstrup states:—

"Meantime the difference between the Alpine data and the Greenland data seems to have grown greater and greater. During the now returned biennial expedition to our northernmost boundary of the west coast of Greenland, the leader of the Expedition, the clever naval officer, Mr. Care Ryder, has measured a progress or a flow of the great glaciers = 99 feet per diem or in twenty-four hours during the summer, and = 30–35 feet in twenty-four hours during winter months."

This, no doubt, will interest many of your Alpine readers.

JOSEPH PRESTWICH.

Shoreham, Sevenoaks, December 17.

"The Mammoth and the Flood."

IN the notice which you have given of my book, which you are good enough to say is, apart from its theories, a valuable work of reference, I should have been more gratified if you had devoted a little space either to stating my arguments or to refuting them, instead of indulging in a rhetorical wail over my backsliding from the orthodox ways of uniformity.

The theories for which I am responsible have been accepted by so many men in the first rank in science in both hemispheres that I am naturally anxious to have them seriously and severely discussed, and I think your critic would allow that I have justified my hope that this will be the case by converging upon my inferences an unusual array of facts.

It was assuredly quite time that someone who disbelieves in "authority in science" should raise a strong protest against the extravagant position which the English school of geology has taken up on this question of uniformity, an extravagance of which students in other branches of science are hardly aware.

The head of the Geological Survey in this country, speaking not long ago with all the authority and responsibility which surround a President of the British Association, committed himself to the following statement:—"From the Laurentian epoch down to the present day, all the physical events in the history of the earth *have varied neither in kind nor in intensity from those of which we now have experience.*"

This was not the opinion of an irresponsible and eccentric student, but of the official mouthpiece of English geology, and with one notable exception—namely, Prof. Prestwich—it has remained, so far as I know, without protest or repudiation, while Prof. Prestwich himself has been treated as a heretic for the views he has so courageously and ably maintained.

My book is meant to challenge the doctrine of uniformity as generally held by English geologists, and which as held here is largely repudiated both in America and on the Continent.

In regard to its many arguments, I cannot defend them in a letter, but I can shortly examine the only one to which your critic directs attention, and which happens to be a very crucial one.

This is the explanation of the existence of a series of mammoths buried in the tundras of Siberia, throughout its entire length, with their soft parts intact. This fact, which has been known for a century, compelled Cuvier long ago to adopt a conclusion which I have simply accepted and enlarged. I state it shortly in the following extract from my work:—"The facts compel us to admit that when the mammoth was buried in Siberia the ground was soft and the climate genial, and that immediately afterwards the same ground became frozen, and the same climate became Arctic, and that they have remained so to this day, and this not gradually and in accordance with some slowly continuous astronomical or cosmical changes, but suddenly and *per saltum.*" I also argue that the only way I can explain the existence of a chain of such carcasses buried many feet deep in *continuous beds of gravel and clay* is by the operation of one cause only, and that a flood of water on a large scale.

Your critic, who I can hardly think has read the part of my book dealing with this issue, says that the carcasses are found in ice. The fact is, *they are never found in ice*, as the Russian explorers have so well shown. The reference to ice in the account of the discovery of the famous Adam's mammoth has been shown by Baer to have been altogether misunderstood, and nothing is more clear than that they are found buried deep in hard frozen gravel and clay.

Secondly, he urges a view which was generally held fifty years ago, but which has been completely dissipated by the elaborate researches of the Russian naturalists, especially the geologist Schmidt, and which I quote at length—namely, that the carcasses have in some way been floated down by the Siberian rivers and buried in their warp. As Schmidt shows, the

Siberian rivers make no deposit, either in winter or summer, which could cover in a mammoth. Nor are the mammoths chiefly found near rivers, but on high ground out of the reach of rivers. When they occur near the rivers, it is generally on the head streams, which could not float such carcasses.

Surely, in criticizing my view of a problem which has been the crux of almost every serious student since the days of Cuvier, your critic might have noticed these now elementary facts. It is not fair to me or to your readers to deal with this difficult question as if it could be settled by a casual reference to causes long ago discarded by such authorities as Brandt and Baer, Schmidt and Schrenck.

I am anxious beyond measure to meet with some criticism that I can reply to, and shall not shrink from the issue being tried by the severest tests.

What I complain of, and others more important than myself share my opinion, is that the only answer forthcoming from uniformitarians to test cases like the one above referred to is, ostrich-like, to put their heads in the sand and to cry out, "Since we are committed to Lyell's theory, it is useless to quote facts against us." This may have done in the fifteenth century, but it will not do now when so many critics are abroad.

May I presume to invite a discussion in your paper on this most interesting question? I cannot forget that it was in your pages I first raised it many years ago.

Bentcliffe, Eccles, December 10. HENRY H. HOWORTH.

In regard to the first part of Mr. Howorth's letter, I must remind him that it was admitted in my review that such a being as an irrational uniformitarian did exist, and was duly smitten in his book.

In regard to the occurrence of mammoth carcasses (not skeletons), I wrote of ice with some hesitation, knowing alleged cases to be open to question, but I mentioned it, because, in my opinion, it would be the most difficult to explain, and the strongest case in favour of Mr. Howorth. Where the carcass is preserved in clay or gravel the difficulty is less. All that seems needed is a flood of rather exceptional character, carrying the dead beast rather far north; then, if this happened at the right season of the year, the body might be buried by other floods before decomposition set in (the temperatures might be always low, though sometimes above 32° F.), and so the body might escape unrotted, until it was finally well entombed. My position was that, though this explanation of the escape of a carcass from destruction, under circumstances not very different from the present, was not easy, the explanation of such a series of catastrophes as Mr. Howorth demanded was much harder. The grounds of this opinion cannot of course be stated in the limits of a letter, nor can I discuss *seriatim* the cases which he cites. So far as my memory serves me (I am writing at a distance from any scientific library) they are not so universally favourable to his view as is stated in his letter.

The remainder of Mr. Howorth's letter is open to the charge which he brings against the review, of being merely rhetorical. *Quis tulerit Gracchos de seditione querentes?*

YOUR REVIEWER.

Centre of Water Pressure.

THE following extremely simple construction for the centre of pressure of a homogeneous liquid on a triangular area occupying any position whatever in the liquid has not (I learn from a high authority on hydrodynamics) been hitherto known, and it may be interesting to some of the readers of NATURE.

Let a particle be imagined to be placed at each vertex of the triangle, its mass being proportional to the depth of this vertex from the surface of the liquid; let G' be the centre of gravity of these particles, and let G be the "centre of gravity" of the triangular area. Then P, the centre of pressure, lies on the line GG' at a distance $\frac{1}{4}GG'$ from G.

There is another almost equally simple way of expressing this result; and of course it is known that there are other ways, more or less practically unmanageable, of representing the position of this point, P, by means of momental ellipses, &c.

GEORGE M. MINCHIN.

R.I.E. College, Cooper's Hill, December 15.

The Recent Earthquakes in Iceland.

ON October 28 last, at 20 minutes past 5 in the morning, two earthquakes occurred at Reykjavík, and reports were soon received as to earthquakes in other districts, especially at Cape Reykjanes. The whole peninsula of Reykjanes is covered with lava streams, and there are many craters and fissures. The extreme point of this peninsula seems in former times to have been the scene of many volcanic eruptions. Tradition tells that long ago the promontory stretched eight miles further to southwest than it does now, and that great earthquakes and volcanic eruptions in the years 1389–90 produced the subsidence of the ancient promontory. The land reached then to Eldey (the Fire Island), or, as the Danes call it, "Melsækken." In historic times ten volcanic eruptions are known to have taken place in the neighbourhood of these rocks.

During the night between October 27 and 28 more than forty shocks were felt at the lighthouse of Cape Reykjanes, nine of the lamps were broken, and the house where the lighthouse keeper lives and a warehouse were damaged. A fissure from south-west to north-east was formed in the rocks 2 yards from the lighthouse; the rocks beneath were cracked in several places, and these cracks go in the same direction as the old fissures associated with volcanic cones. At Eyrarbakki the earthquake was observed at 25 minutes past 5, and proceeded from north-north-west to south-south-east. To north-west the earthquake was felt in Borgar fjord, and as far to the south-east as to Eyjafjöll. This shock was therefore felt over an area of more than 4500 square miles.

A less violent earthquake was felt here in Reykjavík on November 13, at 35 minutes past 9 p.m.

In the year 1882 I published in an Icelandic review, *Andvari*, a list of questions concerning earthquakes, nearly the same as were published in 1880 by Prof. A. Heim for the Earthquake Commission in Switzerland. A similar list of questions has now been printed in the Icelandic newspapers. The questions will also be printed separately, and sent to Icelandic clergymen and others who probably take interest in this subject.

Reykjavik, November 30. TH. THORODDSEN.

The Canary Islands.

NOW that the Canary Islands are rapidly becoming better known as one of the most advantageous health-resorts within easy reach of England, it may be of some interest to mention a few facts concerning diseases in the Archipelago.

The one pre-eminent fact is that the climate seems to modify the virulence of the worst, the most dangerous diseases. Puerperal fever, though rather prevalent, is seldom, I may almost say never, fatal, though I know of cases where the patient has been neglected for several days before medical advice was obtained. Diphtheria is also very prevalent in the large towns, owing to the total absence of the most ordinary sanitary precautions, but it seems always to exist in a mild form. I know of certain families who apparently have it frequently, but this terrible disease seems to be only fatal where the most elementary knowledge of nursing is absent.

Fevers of all kinds are lighter in character. The treatment recommended there by the profession is different from that in vogue in England. For example, it starts by a thorough clearing out of the system by means of somewhat violent purgatives and emetics.

Equable as is the climate by day and night, the natives suffer most from chills, which often end fatally. This, I think, may be in a great measure accounted for by the absence of woollen or silken clothing. Those who visit the Canaries from colder northern latitudes where wool is worn next the skin, and who most wisely continue this habit, do not suffer in this way. It is advisable that every article of clothing worn in the islands be either made of wool or silk. Thus armed, one is almost impregnable to the attacks of any disease of a catarrhal nature. Malaria does not exist. Precautions as to hours of recreation, such as keeping in the house at sundown, are in these islands unnecessary, and one may be out on the hottest day at the hottest hour without fear of sunstroke.

The only disease which in any way can be said to be peculiar to, or prevalent in, the Canary Islands is elephantiasis, which, as your readers well know, does not affect well-nourished inhabitants, and is neither contagious nor infectious.

In Gran Canaria diseases of the stomach and intestines are

common among the peasants. Such are clearly traceable to the national food, *gofio*, which in this island is made of Indian corn.

For phthisis the Canary Islands have been proved of inestimable value, and therefore on this point nothing more need be said. The temperature throughout the year, by day and by night, varies exceedingly little. In my recently-published work on these islands I have gone so fully into this question that I need not recapitulate it here.

I should not have thus ventured to trouble you had I not been asked by some leading members of the medical profession to summarize the facts, bearing upon diseases, scattered through the pages of my book and to add thereto others which I had deemed unsuitable for the general reader. OLIVIA M. STONE.

11 Sheffield Gardens, Kensington, W., December 14.

The Ffynnon Beuno and Cae Gwyn Caves.

MR. SMITH has entirely failed to substantiate the statement made by him in his letter of December 1 (p. 105) concerning the drift over the entrance of the Cae Gwyn Cave, which is 20 feet in thickness and full of ice-scratched boulders, many of large size; therefore I need only say in reply that the Geological Surveyors who surveyed this district have examined the section and have had no hesitation whatever in classifying the deposits in the section with the Glacial beds of the area. In regard to the age of river-drift implements as compared with those found in the cavern, which are identical with the implements found in Kent's cavern and the French caves, I need only quote the remarks of M. Lartet ("Reliquiæ Aquitanicæ," p. 9):—"If some are inclined to attribute to the works of human industry found in the 'Diluvium' or 'Drift' a date more ancient than to those occurring in caves with a similar association of animal remains, we are obliged to remark that such a proposition, expressed as a systematic generalization, is not justifiable in any point of view." . . . "Caves were in truth the first shelter which primitive man would choose, whether driven by instinct or determined by reason."

When Mr. Smith calls the implements found in the gravels at Mildenhall, Neolithic, which others claim to be Palæolithic, and one most eminent authority to be pre-Glacial, I am perfectly justified in saying that the classification of such implements, as defined by Mr. Smith, has no chronological value, and therefore I do not think that anyone is likely to be convinced by his arguments when he is "content to resist the idea of the pre-Glacial age of these caves on purely archæological grounds."

HENRY HICKS.

Hendon, December 23.

Distorted Earth Shadows in Eclipses.

WITH reference to the peculiar appearance of the earth's shadow in the lunar eclipse of August 3 of this year, and noted by "H. H." and "M. C." (see NATURE, vol. xxxvi. pp. 367 and 413), it may be of interest to record a similar distortion observed by Capt. A. E. Barlow, on the s.s. *Nizam*, at Suez, on August 23, 1877. The following entry appears in his meteorological log:—

"The eclipse of August 23. The moon as seen at midnight at Suez. Weather fine starlight. A few cir.-c. (amount 3) travelling from northward."

The shadow was irregular and jagged as in "M.C.'s" description. HENRY TOYNBEE,
Marine Superintendent.

Meteorological Office, December 22.

DR. BALFOUR STEWART, F.R.S.

IN the genial Manchester Professor the scientific world has lost not only an excellent teacher of physics but one of its ablest and most original investigators. He was trained according to the best methods of the last generation of experimentalists, in which scrupulous accuracy was constantly associated with genuine scientific honesty. Men such as he was are never numerous; but they are the true leaders of scientific progress:—*directly*, by their own contributions; *indirectly*, though (with rare exceptions) even more substantially, by handing on to their students the choicest traditions of a past age, mellowed by time and enriched from the experience of the present. The name of Stewart will long be remembered for more than one striking addition to our knowledge, but his patient and reverent spirit will continue to impress for good the minds and the work of all who have come under its influence.

He was born in Edinburgh, on November 1, 1828, so that he had entered his sixtieth year. He studied for a short time in each of the Universities of St. Andrews and Edinburgh, and began practical life in a mercantile office. In the course of a business voyage to Australia his particular taste for physical science developed itself, and his first published papers:—"On the adaptation of the eye to different rays," and "On the influence of gravity on the physical condition of the Moon's surface":—appeared in the *Transactions of the Physical Society of Victoria* in 1855. On his return he gave up business for science, and resumed study under Kelland and Forbes, to the latter of whom he soon became Assistant. In this capacity he had much to do with the teaching of Natural Philosophy on occasions when Forbes was temporarily disabled by his broken health. During this period, in 1858, Stewart was led to his well-known extension of Prévost's *Law of Exchanges*, a most remarkable and important contribution to the theory of Radiation. He seems to have been the first even to suggest, from a scientific stand-point, that radiation is not a mere surface phenomenon. With the aid of Forbes' apparatus, then perhaps unequalled in any British University, he fully demonstrated the truth of the conclusions to which he had been led by theory; and the award of the Rumford Medal by the Royal Society, some years later, showed that his work had been estimated at its true value, at least in the scientific world. In fact his proof of the necessary equality between the radiating and the absorbing powers of every substance (when divested of some of the unnecessary excrescences which often mask the real merit of the earlier writings of a young author) remains to this day the simplest, and therefore the most convincing, that has yet been given.

Radiant Heat was, justly, one of Professor Forbes' pet subjects, and was therefore brought very prominently before his Assistant. Another was Meteorology, and to this Stewart devoted himself with such enthusiasm and success that in 1859 he was appointed Director of the Kew Observatory. How, for eleven years, he there maintained and improved upon the memorable labours of Ronalds and Welsh needs only to be mentioned here:—it will be found in detail in the *Reports of the British Association*. Every species of inquiry which had to be carried out at Kew:—whether it consisted in the testing of Thermometers, Sextants, Pendulums, Aneroids, or Dipping-Needles, the recording of Atmospheric Electricity, the determination of the Freezing-Point of Mercury or the Melting-Point of Paraffin, or the careful study of the peculiarities of the Air-Thermometer:—received the benefit of his valuable suggestions and was carried out with his scrupulous accuracy.

About twenty years ago Stewart met with a frightful railway accident, from the effects of which he did not fully recover. He was permanently lamed, and sustained severe injury to his constitution. From the vigorous activity of the prime of life he passed, in a few months, to grey-headed old age. But his characteristic patience was unruffled, and his intellect unimpaired.

His career as Professor of Physics in the Owens College has been, since his appointment in 1870, brilliantly successful. It has led to the production of an excellent treatise on *Practical Physics*, in which every necessary detail is given with masterly precision, and which contains (what is even more valuable, and could only have been secured to the world by such a publication) the matured convictions of a thorough experimenter as to

the choice of methods for the attack of each special Problem.

His *Elementary Physics*, and his *Conservation of Energy*, are popular works on physics rather than scientific treatises:—but his *Treatise on Heat* is one of the best in any language, a thoroughly scientific work, specially characteristic of the bent of mind of its Author.

Stewart published, in addition to his *Kew Reports*, a very large number of scientific memoirs and short papers. Many of these (notably the article in the *Encyc. Brit.*, 9th edn.) deal with Terrestrial Magnetism, in itself as well as in its relations to the Aurora and to solar disturbances. A valuable series of papers, partly his own partly written in conjunction with De la Rue and Lœwy, deals with Solar Physics. His paper on the *Occurrence of Flint Implements in the Drift* (*Phil. Mag.* 1862, I.) seems to have been ignored by the "advanced" geologists, one of whose pet theories it tends to dethrone; and to have been noticed only by physicists, especially Sir W. Thomson, whose beautiful experiments have done so much to confirm it. His paper on *Internal Radiation in Uniaxal Crystals*, to which Stokes alone seems to have paid any attention, shows what Stewart might have done in Mathematical Physics, had he further developed the genuine mathematical power which he exhibited while a student of Kelland's.

I made Stewart's acquaintance in 1861, when he was the first-appointed Additional Examiner in Mathematics in the University of Edinburgh, a post which he filled with great distinction for five years. A number of tentative investigations ultimately based upon our ideas as to possible viscosity of the luminiferous medium, effect of gravitation-potential on the physical properties of matter, &c., led to the publication of papers on *Rotation of a disc in vacuo*, *Observations with a rigid spectroscope*, *Solar spots and planetary configurations*, &c. These, as well as our joint work called *The Unseen Universe*, have been very differently estimated by different classes of critics. Of course I cannot myself discuss their value. There is, however, one of these speculations, so closely connected with Stewart's Radiation work as to require particular mention, especially as it seems not yet to have received proper consideration, viz. *Equilibrium of Temperature in an enclosure containing matter in visible motion.* (NATURE, 1871; iv. 331.) The speculations are all of a somewhat transcendental character, and therefore very hard to reduce to forms in which they can be experimentally tested; but there can be no doubt that Stewart had the full conviction that there is in them all an underlying reality, the discovery of whose exact nature would at once largely increase our knowledge.

Of the man himself I cannot trust myself to speak. What I *could* say will easily be divined by those who knew him intimately; and to those who did not know him I am unwilling to speak in terms which, to them, would certainly appear exaggerated.

P. G. TAIT.

CHRISTMAS ISLAND.

PROFESSOR NEWTON sends us the following extracts from a letter received by him from Mr. J. J. Lister, M.A., St. John's College, Cambridge, the naturalist on board H.M.S. *Egeria*, Commander Aldrich, R.N., describing the recent visit to that little-known island:—

"We left Batavia on Tuesday, September 27, about 5 a.m., and were in the Straits of Sunda by the afternoon. We saw the hills on the Java side clearly, scored by many steep-sided valleys, and the green of the fields contrasting brightly with the red volcanic earth. Behind these nearer hills one of the great conical mountains loomed out every now and then from his covering of clouds. To the westward, and more distant, a high volcanic peak on the main island of Sumatra rose above nearer islands, and later in the afternoon we saw the simple conical mass of Krakatão. Next day we were bouncing about in deep blue water, as we steamed south against a head-wind—a change after the quiet sailing over the pale green shallow seas in which we had been since we entered the Straits of Malacca. On Friday, September 30, we reached Christmas Island. The first we saw of it was a long line against the south-east horizon, with a shallow saddle in the middle and a gradual rise at either end—that to the west being the higher. On nearer approach the island was seen to be uniformly covered with trees, with a low cliff, much undermined at the water's edge; above this a gradual slope leads to another steep ascent, which in some places, especially at the projecting headlands, is a bare cliff, in others covered with trees. From this there is a gradual rise to the top. We found that there is a cap of coral limestone over the whole island. The top is formed of gray pinnacled masses with steep fissures between them, and the surface of the rock is worn into a rough honey-comb with sharp points and ridges which break under foot and show the glistening white rock. On the slope of the island this rock forms horizontal terraces, with a rough slope of pinnacled masses or a sheer cliff leading down from them, and these seemed to be in a general way continuous at the same level along the side of the island. I suppose they mark the pauses in its gradual elevation during which a fringing reef has formed. Some pieces of rock, apparently volcanic, were picked up at Flying-fish Cove, but it was not found where they had fallen from.

"No stream or standing water was found. Apparently all the rain that falls soaks into the porous rock at once. The vegetation, however, looked fresh and green, and the under parts of fallen logs were sodden with moisture. On two of the nights during the ten days we were there, there was heavy rain; otherwise we had fine weather. Many of the trees are tall, reaching 150 to 170 feet or more, and some of them have vertical buttresses at the base, which wind about horizontally and give off secondary buttresses. They are often laden with great clumps of birds'-nest ferns, as well as with other ferns, orchids, and parasitical trees, and their trunks are festooned with long straight lianas. I only found two orchids with flowers out, but these were small and inconspicuous. Along the shore there are tangled thickets of screw pines, and another kind grows on the higher part. A large proportion of the trees bear edible fruits. Altogether I am sending home some fifty kinds of flowering plants and fifteen of ferns.

"The rat (*Mus macleari*) swarms on the island. They come out at dusk, and run about, in and out of the tents that were pitched by the shore, through the night. There is another kind of rat which is larger and black, except where the scanty fur on the feet allows the pale skin to show. There is also a shrew mouse, whose short shrill squeak may often be heard in the woods. I caught three of them one night in a pitfall. Several specimens of the fruit-eating bat (*Pteropus natalis*) were obtained, including males, which have no pale-coloured tippet, as Mr. Thomas [P.Z.S., 1887, p. 512] thought might possibly be the case. There is a small insectivorous bat in the island, but I did not succeed in getting one.

"The large fruit-eating pigeon (*Carpophaga whartoni*) is very common. They congregate in the fruit-bearing trees, and may then be shot by the dozen. They are excellent eating, and supplied fresh meat for the ship.

"There is a small dove—brown, with a rich bronzy-green on the back and wings—which is very common. Their habits are remarkably in keeping with their colouring. On trees they are restless and seldom seen, but on the ground, among fallen brown and green leaves, where their colour makes them very inconspicuous, they seem to have no fear. I shot seven one morning close to our place: they were feeding in pairs on fallen berries, and

when one of a pair was shot, the other went on feeding as though nothing had happened.

"The thrush (*Turdus erythropleurus*) is very abundant, and as tame as possible. None of my specimens show any mottling, but Capt. Aldrich told me that he saw one with the breast mottled. The bill and feet are as yellow as a cock blackbird's. I heard no *song*, but they often give a 'chick——chick——chick—chick-chick-chick,' quickening time at the finish.

"Parties of twelve to twenty of a species of *Zosterops* were very common. They had just-fledged young ones among them.

"The other birds we obtained were two hawks, an owl, a swift, a heron, a plover, and a sandpiper. Besides these, frigate-birds, gannets, boobies, and boatswain-birds of two kinds were everywhere abundant.

"We obtained three kinds of lizards, and the *Typhlops* which was found before, but no tortoises. We saw a turtle making off down the beach early one morning, but it got into the sea before it could be turned over.

"We saw no frogs, and heard none.

"We found five kinds of land-shells, four of butterflies, a few moths, and some eighteen species of beetles, besides spiders, centipedes, &c. I have one of the hawks alive, which I hope to be able to bring home to England. . . . . "J. J. LISTER."

Accounts have been received from Captain Aldrich, R.N., of H.M. surveying-vessel *Egeria*, of a recent visit to Christmas Island in the Indian Ocean, made in consequence of the interest attaching to the small collection recently brought thence by Captain Maclear, R.N., (see NATURE, vol. xxxvi. p. 12). Mr. J. J. Lister kindly volunteered to act as naturalist, and proceeded from England to Colombo, whence he took a passage in the *Egeria* for the purpose of collecting.

Captain Aldrich states that the highest point of the island was reached at the expense of considerable labour, but without as much difficulty as was anticipated. This point is 1200 feet high, and not, as was before incorrectly stated, 1580 feet.

The island is coral-clad to the very top, the actual summit being a block of coralline limestone, worn and undermined. No rock other than of a calcareous nature was met with in the island, though a diligent search was made, and holes dug where the soil appeared thickest.

Three tiers of cliffs, probably marking sea-levels, intervene between the top of the existing sea cliffs and the summit. Breaches in these cliffs afforded means of scaling them, aided by the numerous aërial roots of the trees with which the island is densely covered.

Between the cliffs the ground rises irregularly, being covered in some places with soil apparently deep, intermixed with fragments of coral. Tangled jungle and high forest grow everywhere. The vertical rise to the summit where ascended takes place in the following manner, as described by Captain Aldrich :—

Coast cliff	30	feet vertical.
Moderate slope	90	,,
First inland cliff	85	,,
Moderate slope	250	,,
Second inland cliff, Slope, Third inland cliff	95	,,
Steep slope of rough ground	650	,,

The total horizontal distance is about 5000 feet.

Christmas Island therefore appears to be a remarkable instance of the complete casing with coral of an island which, from the time that its nucleus first came within the reef-building zone, has been steadily subjected to a movement of upheaval, varied by pauses, during which the cliffs were eroded by the sea. So far as I am aware, no case of similar magnitude has yet been recorded.

The collections now on their way to England are, it is feared, not so varied as was anticipated from the samples of life brought home by the *Flying Fish*.

A considerable number of interesting photographs were obtained by the officers, and accompany Captain Aldrich's report, which will be published.

The *Egeria* has obtained a line of soundings across the hitherto unfathomed area of the southern Indian Ocean, between the Strait of Sunda and Mauritius, but no details have as yet come to hand.

December 17. W. J. L. WHARTON.

TIMBER, AND SOME OF ITS DISEASES.[1]

II.

THE enormous variety presented by the hundreds of different kinds of woods known or used in different countries depends for the most part on such peculiarities as I have referred to above, together with some others which have not as yet been touched upon. Everybody knows something of the multitudinous uses to which timber is put, and a little reflection will show that these uses are dependent upon certain general properties of the timber. Speaking broadly, the chief properties are its weight, hardness, elasticity, cohesion, and power of resisting strains, &c., in various directions, its durability in air and in water, and so forth; moreover, special uses demand special properties of other kinds also, and the colour, closeness of texture, capacity for receiving polish, &c., come into consideration.

Now, there is no doubt that the structure of the wood as formed by the cambium is the chief factor in deciding these technological characters: it is not the only factor, but it is the most important one. Consequently no surprise can be felt that those who are interested in timber have of late years turned their attention to this subject with a view to ascertain as much as possible about this structure, and to see whether it can be controlled or modified, what dangers it is subject to, and how far a classification of timbers can be arrived at. The more the subject is studied, the more interesting and practically important the matter becomes. The results already obtained (though the study is as yet only in its infancy), have thrown brilliant light on several burning questions of physiology—as witness the researches of Sachs, Hartig, Elfving, and Godlewski, on that old puzzle, to account for the ascent of water in tall trees. The study is, moreover, of first importance for the comprehension of the destruction of timber, due to "dry-rot" and the parasites which cause diseases in standing trees, as is shown by the brilliant researches of Prof. R. Hartig on the destruction of timber by Hymenomycetes; and again as yielding trustworthy information as to the value of different kinds of timber in the arts, and enabling us to recognize foreign or new woods of value. In support of this statement it is only necessary to call attention to the "Manual of Indian Timbers," prepared for the Indian Government by Mr. Gamble; or to refer to the beautiful series of wood-sections prepared by Nördlinger.

It is, of course, impossible in an article like the present to do more than touch upon a few of the more interesting points in this connection; but I may shortly summarize one or two of the more striking of these peculiarities of timbers, if only to show how well worth further investigation the matter is.

Many timbers, from both tropical and temperate climates, exhibit the so-called "annual rings" on the transverse section; but this is not the case with all. Most European timbers, for instance, are clearly composed of such layers; but in some cases the layers ("rings" on the transverse section) are so narrow and

[1] Continued from p. 186.

numerous that the unaided eye can scarcely distinguish them, or the differences between the spring and autumn wood are so indistinctly marked that they may appear to be absent, or are at least obscure, as in the Olive, Holly, and Orange, for instance. It is in the tropics, however, that timber without annual rings is most common, chiefly because the seasons of growth are not sufficiently separated by periods of rest to cause the

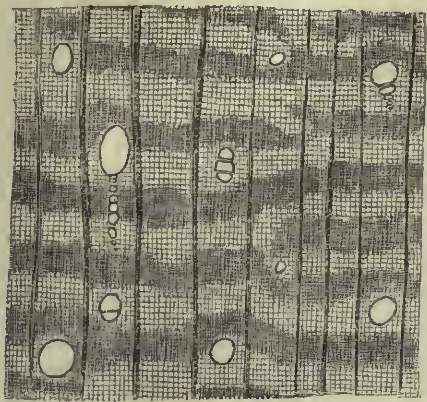

FIG. 7.—Transverse section of the wood of *Pongamia glabra*, Vent., selected to show a type of timber not uncommon in India. No distinct annual rings appear, but the wood is traversed by wavy bands of tissue, which may run into one another or not. The vessels ("pores") are few and scattered, and differ in size; the medullary rays well marked, but not large. To this type—differing in other details—belong many species of figs, acacias, and other Asiatic Leguminoseæ, &c.

formation of sharply-marked zones, corresponding to spring and autumn wood, *e.g.* some Indian Leguminosæ, &c. Zones of tissue of other kinds often occur in such timbers, and have to be understood, since they affect the properties of the wood very differently, *e.g.* some of the Figs.

None of the conifers or dicotyledonous trees, however, are devoid of medullary rays, and distinctive characters

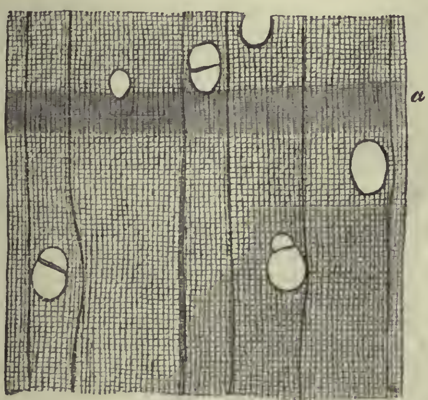

FIG. 8.—Transverse section of wood of *Tamarindus indica*, Linn., selected to show a not uncommon type of Asiatic timber. The annual rings are indistinct, but occasionally indicated by denser tissue (*a*). The vessels are fairly large and few, and scattered much as in Fig. 7, but there are no such broad bands of cells as there.

are based on the breadth and numbers of these: as examples for contrast may be cited the fine rays of the Pines and Firs, and the coarse obvious ones of the Oaks.

Again, the prominence or minuteness, or even (Coniferæ) absence, of vessels in the secondary wood afford characters for classification. The contrast between the extremely small vessels of the Box and the very large ones of some Oaks and the Chestnut, for instance, is too striking to be overlooked. Then, again, in some timbers the vessels are distributed more or less equably throughout the "annual ring," as in the Alder, some Willows and Poplars, &c.; whereas in the Chestnut and others they are especially grouped at the inner side of the annual zone (*i.e.* in the spring wood), and in some cases these

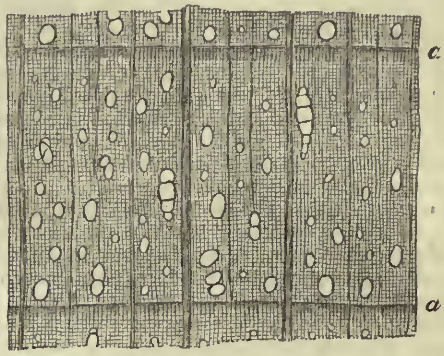

FIG. 9.—Transverse section of the wood of *Acer pseudo-platanus*, selected to show a type of timber common in Europe. The annual rings (*a*) are well-marked and regular. The vessels are small and numerous, and scattered somewhat equally over the whole breadth of the ring. The medullary rays are numerous, some broad, some fine. Many European timbers (beech, hornbeam, lime, &c.) agree with this type, except in details.

groupings are such as to form characteristic figures on the transverse section, as in some Oaks, *Rhamnus*, &c. In the woodcuts (Figs. 7–10) I have given four examples illustrating a few of the chief points here adverted to.

Passing over peculiar appearances due to the distribution of the wood-parenchyma between the vessels, as

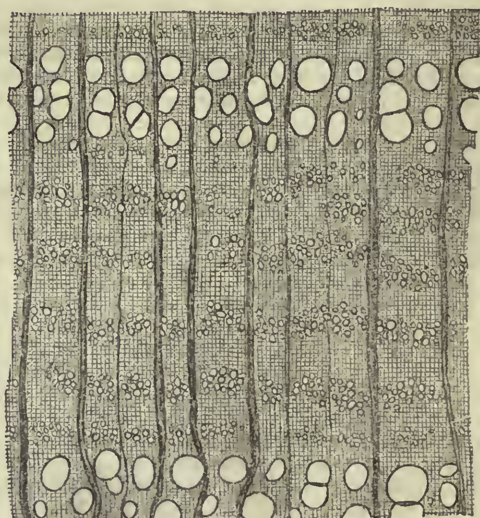

FIG. 10.—Transverse section of wood of the common elm (*Ulmus campestris*), selected as a common type of European timber. The annual rings are very distinct, owing to the large vessels in the spring wood; the vessels formed during the summer and autumn are grouped in bands or zones. The medullary rays are numerous, but not very broad. The oak, ash, chestnut, and others agree in the main with this type, differing chiefly in the *mode of grouping* of the smaller vessels, and in the *breadth* of the medullary rays.

exemplified by the Figs and the Maples, as well as minor but conspicuous features which enable experts to recognize the timber of certain trees almost at a glance, I may now proceed to indicate a few other peculiarities which distinguish different timbers.

The weight of equal volumes of different woods differs

more than is commonly supposed, and there are certain details to be considered in employing weight as a criterion which have not always been sufficiently kept in mind.

A cubic foot of "seasoned" timber of the Indian tree *Hardwickia binata* weighs about 80 lbs. to 84 lbs., while a cubic foot of *Bombax malabaricum* may weigh less than 20 lbs., and all gradations are possible with various timbers between these or even greater extremes. If we keep in mind the structure of wood, it is evident that the weights of equal volumes of merely seasoned timber will yield only approximate results. For even if the seasoning, weighing, &c., are effected in a constant atmosphere, woods which differ in "porosity" and other properties will differ in the extent to which they absorb moisture from damp air or give it up to dry air.

In our climate, timber which is felled in April or May, generally speaking, contains much more water than if felled in July and August: it is, in fact, no uncommon event to find that about half the weight, or even more, of a piece of recently felled timber is due to the water it contains. If this water is driven off by heat, and the piece of wood thoroughly dried, the latter will be found to weigh so much less, but it will increase in weight gradually as it imbibes moisture again.

Now it happens that the weight of a piece of timber, compared with that of an equal volume of some standard substance—in other words, the specific weight—is of very great importance, because several other properties of wood stand in relation with it, *e.g.* the hardness, durability, value as fuel, tendency to shrink, &c. Fresh-cut timber in very many cases contains on an average about 45 to 50 per cent. of its weight of water, and if "seasoned" in the ordinary way this is reduced to about 15 to 20 per cent.; but the fresh timber also contains air, as may easily be shown by warming one end at the fire or in hot water and watching the bubbles driven out, and the seasoned timber contains less water and more air in proportion, so that we see how many sources of error are possible in the usual weighings of timber. At the same time, many comparative weighings of equal volumes of well-seasoned timber do yield results which are of rough practical use.

The fact is that the so-called "specific weight" of timber, as usually given, is not the specific gravity of the wood-substance, but of that *plus* entangled air and water. It is interesting to note that, although we associate the property of floating with wood, timber deprived of its air will sink rapidly, being about half as heavy again as water, volume for volume.

The point just now, however, is not to discuss these matters in detail, but rather to indicate that, other things equal, the density of a piece of timber will be greater, the more of that closely-packed, thick-walled autumn wood it contains; while the timber will be specifically lighter and contain more air when dry, the greater the proportion of the looser, thin-walled spring wood in its "annual rings." In other words, if we could induce the cambium to form more autumn wood and less spring wood in each annual ring, we could improve the quality of the timber; and, in view of the statement which has been made, to the effect that large quantities of timber of poor quality reach the Continental wood-yards every year, this is obviously an important question, or at any rate may become one. The remainder of this article must be devoted to this question alone, though it should be mentioned that several other questions of scientific and practical importance are connected with it.

The first point to notice is that the cambium-cells, like all other living cells which grow and divide, are sensitive to the action of the environment. If the temperature is too high or too low, their activity is affected and may even be brought to an end; if the supply of oxygen is too small, their life must cease, since they need oxygen for respiration just as do other living cells; if they are deprived of water, they cannot grow—and if they cease to grow they cannot divide, and any shortcomings in the matter of water-supply will have for effect a diminution of activity on the part of the cambium. The same is true of the supply of food-substances: certain mineral salts brought up from the soil through the roots, and certain organic substances (especially proteids and carbo-hydrates) prepared in the leaves, are as necessary to the life of a cambium-cell as they are to the life of other cells in the plant. Now, since the manufacture of these organic substances depends on the exposure of the green leaves to the light, in an atmosphere containing small quantities of carbon-dioxide, and since the quantities manufactured are in direct relation to the area of the leaf-surface—the size and numbers of the leaves—it is obvious that the proper nourishment of the cambium is directly dependent on the development of the crown of foliage in a tree. Again, since the amount of water (and mineral salts dissolved in it) will vary with the larger or smaller area of the rootlets and absorbing root-hairs (other things equal), this also becomes a factor directly affecting our problem. Of the interdependencies of other kinds between these various factors we cannot here speak, since they would carry the argument too far for the space at command; some of them are obvious, but there are correlations of a subtle and complex nature also.

First as to temperature. The dormant condition of the cambium in our European winter is directly dependent on the low temperature: as the sun's rays warm the environment, the cambial cells begin to grow and divide again. The solar heat acts in two ways: it warms the soil and air, and it warms the plant. Wood, however, is a bad conductor of heat, and the trunk of a tree is covered by the thick corky bark, also an extremely bad conductor, and it would probably need the greater part of the early summer to raise the temperature of the cambium sufficiently for activity in the lower parts of a tree by direct solar heat: the small twigs, on the contrary, which are covered by a thin layer of cortex, and epidermis, are no doubt thus warmed fairly rapidly, and their early awakening is to be referred to this cause. The cambium in the trunk, however, is not raised to the requisite temperature until the water passing up through the wood from the roots is sufficiently warm to transmit some of the heat brought with it from the soil to the cells of the cambium. This also is a somewhat slow process, for it takes some time for the sun's rays to raise the temperature of the soil while the days are short and the nights cold. Hartig has shown that the cambium in the lower part of the trunk of a tree may be still dormant three weeks or a month after it has begun to act in the twigs and small branches; and it has also been pointed out that trees standing in open sunny situations begin to renew their growth earlier than trees of the same species growing in shady or crowded plantations, where the moss and leaf-mould, &c., prevent the sun from warming the soil and roots so quickly. These observations have also a direct bearing on the later renewal of cambial activity in trees growing on mountains or in high latitudes. Moreover, though I cannot here open up this interesting subject in detail, these facts have their connection with the dying off of temperate trees in the tropics, as well as with the killing of trees by frost in climates like our own. One important practical point in this connection may be adverted to. Growers of conifers are well aware that certain species cannot be safely grown in this country (or only in favoured spots) because the sun's rays rouse them to activity at a time when spring frosts are still common at night, and their young tissues are destroyed by the frosts. Prof. R. Hartig has pointed out a very instructive case. The larch is an Alpine plant, growing naturally at elevations where the temperature of the soil is not high enough to communicate the necessary stimulus to the cambium until the end of May or June.

Larches growing in the lowlands, however, are apt to begin their renewed growth in April, and frosted stems are a common result, a point which (as the renowned botanist just referred to also showed) has an important bearing on that vexed question—the "larch-disease."

The supply of oxygen to the cambium is chiefly dependent on the supply of water from the roots, and the aëration of the stem generally. The water begins to ascend only when the soil is warm enough to enable the root-hairs to act, and new ones to be developed, and the supply of mineral salts goes hand in hand with that of water.

Now comes in the question of the sources of the organic substances. There is no doubt that the cambium at first takes its supply of food-materials from the stores which have been laid by, in the medullary rays, &c., at the conclusion of the preceding year; and it is known that special arrangements exist in the wood and cortex to provide for this when the water and oxygen arrive at the seat of activity.

Assuming that all the conditions referred to are favourable, the cambium-cells become filled with water in which the necessary substances are dissolved, and distended (become turgid, or turgescent, as it is technically called) sufficiently for growth. Speaking generally, and with reference chiefly to the trunk of the tree, which yields the timber, the distension of the cells is followed by growth in the direction of a radius of the stem, and division follows in the vertical plane, tangential to the stem. Then the processes already described with reference to Fig. 5 repeat themselves, and the trunk of the tree grows in thickness.

Now it is obvious that the thickening of the mass of timber inside the cylinder of cambium must exert pressure on the cortex and bark—must distend them elastically, in fact—and some ingenious experiments have been made by De Vries and others to show that this pressure has an effect in modifying the radial diameter of the cells and vessels formed by the cambium. Several observers have promulgated or accepted the view that the differences between so-called spring and autumn wood are due to the variations in pressure of the cortex on the cambium, but the view has lately gained ground, based on experimental evidence, that these differences are matters of nutrition, and a recent investigator has declared that the thick-walled elements and small sparse vessels characteristic of autumn wood can be produced, so to speak, at will, by altering the conditions of nutrition.

It is authoritatively stated that the pines of the cold northern countries are preferred for ships' masts in Europe, and that the wood-cutters and turners of Germany prize especially the timber of firs grown at high elevations in the Bavarian Alps. Now the most striking peculiarity of the timbers referred to is the even quality of the wood throughout: the annual rings are close and show less of the sharp contrasts between thin-walled spring wood and thick-walled autumn wood, and Hartig suggested that this is due to the conditions of their nutrition, and in the following way. The trees at high elevations have their cambium lying dormant for a longer period, and the thickening process does not begin in the lower parts of the trunk until the days are rapidly lengthening and the sun's rays gaining more and more power: the consequence is that the spring is already drawing to a close when the cambium-cells begin to grow and divide, and hence they perform their functions vigorously from the first.

One of the most interesting experiments in this connection came under my observation this summer, owing to the kindness of Prof. Hartig. There is a plantation of larches at Freising near Münich, with young beeches growing under the shade of the larches. The latter are seventy years old, and are excellent trees in every way. About twenty years ago these larches were deteriorating seriously, and were subsequently "under-planted" with beech, as foresters say—*i.e.* beech-plants were introduced under the shade of the larches. The recovery of the latter is remarkable, and dates from the period when the under-planting was made.

The explanation is based on the observation that the fallen beech-leaves keep the soil covered, and protect it from being warmed too early in the spring by the heat of the sun's rays. This delays the spring growth of the larches: their cambium is not awakened into renewed activity until three weeks or a month later than was previously the case, and hence they are not severely tried by the spring frosts, and the cambium is vigorously and continuously active from the first.

But this is not all. The timber is much improved: the annual rings contain a smaller proportion of soft, light spring wood, and more of the desirable summer and autumn wood consisting of closely-packed, thick-walled elements. The explanation of this is that the spring growth is delayed until the weather and soil are warmer, and the young leaves in full activity; whence the cambium is better nourished from the first, and forms better tracheides throughout its whole active period. Such a result in itself is sufficient to repay the investigations of the botanist into the conditions which rule the formation of timber, but this is by no means the only outcome of researches such as those carried on so assiduously by Prof. Hartig in Münich, and by other vegetable physiologists.

It is easy to understand that the toughness, elasticity, and such like qualities of a piece of timber, depend on the character of the tracheides, fibres, &c., of which it is chiefly composed. Investigations are showing that the length of such fibres differs in different parts of the tree. Sanio has already demonstrated that in the Scotch pine, for instance, the tracheides differ in length at different heights in the same trunk, becoming longer as we ascend, and also are longer in the outer annual rings than in the inner ones as the tree grows older, up to a certain period; and this is in accordance with other statements to the general effect that for many years the wood improves, and that better wood is found at the base of the trunk.

However, it is impossible to pursue these subjects in all their details: my object is served by showing how well worthy of the necessary scientific study is timber even to those who are only concerned with it in its usual conditions, and within those limits of variation in structure and function which constitute health. The importance of the subject in connection with the modern development of biology along the grand road of comparative physiology, does not need insisting upon here. It will be the object of further articles to show how it is, if possible, still more important and interesting to know the structure and functions of healthy timber, before the practical man can understand the diseases to which timber is subject. At the same time it must be clearly borne in mind that these are but sketches of the subject; for it is as true of trees and their diseases as it is of men and human diseases, if you would be trainers and doctors you must know thoroughly the structures and peculiarities of the beings which are to be under your care.

H. MARSHALL WARD.

(*To be continued.*)

NOTES.

THE collections of natural history lately forwarded to the British Museum by Dr. Emin Pasha, from Central Africa, will be described at the meeting of the Zoological Society on January 17. The specimens have been determined by various experts in the different branches of natural history to which they belong. Mr. Oldfield Thomas has prepared a paper on the mammals, amongst which are examples of a remarkable

new species of *Hyrax*. Captain Shelley will contribute a paper on the series of birds, which also embraces several new forms. The Lepidoptera have been worked out by Mr. A. G. Butler, and contain specimens of thirteen butterflies new to science, Mr. Edgar A. Smith has examined the fresh-water shells which Dr. Emin Pasha obtained on the Lake Albert Nyanza. They are referable to five species only, but three of these, as might have been expected from the novel locality in which they were obtained, appear to be new to science.

THE Physical Society, of which Dr. Balfour Stewart was President, was represented at his funeral by three of its members: Mr. J. Johnstone Stoney, Prof. G. F. Fitzgerald, and Prof. W. F. Barrett.

IN a lecture lately delivered by Sir Douglas Galton at the Parkes Museum, he drew attention to the increase every year of fog and smoke in London, and to the possibility of their abatement. Dr. Russell's experiments, carried out at St. Bartholomew's Hospital, for the Meteorological Council, showed that the City rain contained twice as much impurity as that collected in the suburbs. That is to say, if the City rain were diluted with nearly an equal bulk of water, we should have the rain of the suburbs. He referred to the experiments of Prof. Lodge with a bell-jar filled with smoke, which is quickly deposited by a discharge of electricity, and argued that by disturbing the electrical condition of the air by kites or balloons, rain may be caused, and by this means the fog dislodged. Failing this, nothing remains but to use gas instead of open stoves, but this method at present costs about four times as much as coal.

WE learn from the *Annales Industrielles* that a mine-shaft is being successfully sunk by M. Alexandre, of the Houssu Company, in Belgium, through a stratum of moist sand 12 metres thick, met with at 70 metres depth, by the Poetsch method, which consists in freezing the sand, then excavating it like rock. In the present case ten iron tubes (with cutting crown) are inserted in the sand at about 1 metre interval, penetrating the coal below. Into these are put other tubes, through which is passed a very cold liquid to return by the larger tubes (generally chloride of magnesium cooled by expansion of ammonia). The sand is frozen more than 3 metres round the tubes. It has the appearance of a rock harder than the compact chalk of the English Channel tunnel; it is sparkling, and speckled with particles of coal. The chloride of magnesium, injected at $-14°$ C., returns at $-12°$. A thermometer inserted 10 centimetres in the stratum read $-8°$. M. Poetsch's method was lately applied to making a tunnel at a small depth under part of the city of Stockholm.

WATERSPOUTS are sometimes seen on the Lake of Geneva, and M. Dufour has made a study of one which occurred on August 19, about 7.30 a.m. (*Arch. des Sciences*). It seems to have arisen on the lake at the meeting of two winds, one from the south, in the eastern part of the lake, and the other from the west, in the western; and its path was along the line of demarkation, changing direction somewhat as it neared the northern shore. Some testified to a rising of the water, which was in violent rotation (in the direction of the hands of a watch). The base of the column was like whirling opaque smoke, which rose in widening spiral, lost above in the cloud. The column was considerably inclined, the upper part advancing more quickly than the lower. In the rear was heavy rain. It is estimated that the *trombe* was about 2 to 3 metres in diameter at foot, and about 106 metres high, and its rate of progress about 760 metres per minute (the speed of an express train). On reaching the shore it disappeared, doing no harm either to vineyard or railway, and had the look of a serpent drawing in its tail. The weather was very variable that day, from hour to hour, and from one part of the lake to another. There was no thunder nor lightning.

THE United States Monthly Weathly Review for September last shows nine depressions in the Atlantic Ocean, of which five were of tropical or sub-tropical origin. Three advanced eastwards from the American Continent north of 45° N., and one appeared over the British Isles. Three of the depressions moved across the Atlantic to Western Europe. As compared with September 1886, there was a slight decrease in the quantity of ice reported; this year the northern limit was lat. 45° 37′ N., and the eastern limit long. 40° 50′ W.

THE Port Officer of Madras has given notice, dated September 22, 1887, that the following storm-signals have been adopted at the ports of the Madras Presidency, instead of the flags hitherto used:—Day-signals: a ball indicates the probable approach of dangerous weather; a drum indicates that a cyclone is likely to approach the port; a cone, apex upwards, at the flag-staff of the port, indicates that it is decided the shipping shall be ordered to sea. Night-signals: three lights, hoisted vertically one above the other, indicate the probable approach of dangerous weather; two lights, hoisted vertically one above the other, indicate that a cyclone is likely to approach the port; three bright lights, hoisted triangularly, one at the mast-head and one at each yard-arm of the flag-staff of the port, indicate that it is decided the shipping shall be ordered to sea.

AT the conclusion of the Colonial and Indian Exhibition some specimens of the American lake-trout (*S. namaycush*), which had been hatched and reared in the Canadian Section, were put in a tank, where they prospered. One fish especially prospered, surpassing the others in size by an inch. In the course of this year they have all disappeared, with the exception of the one referred to, whose colossal form accounts for its missing congeners, which evidently became its prey. Mr. W. August Carter, of the National Fish-Culture Association, states that about 50,000 of these fish were hatched at South Kensington two years ago, when he observed them attack one another soon after leaving their sac. There is a great diversity of growth among them—greater than that which exists among British trout.

A CURIOUS incident is reported by Mr. William Burgess, proprietor of the Midland Counties Fish-Culture Establishment. He states that a pond constructed by him last March, measuring 50 feet by 30 feet, which is entirely isolated from other similar ponds, was shortly after its formation found to be populated with trout fry in their alevin stage. No fish of any kind had been placed in the pond, and none could have entered it, the inlet and outlet being blocked with perforated zinc of a very fine mesh. The soil of the pond in question was excavated from a brook where trout must have previously spawned, and the ova, although buried in mud and flung heedlessly about, survived, and the fry came to life when water had been let into the pond. This is another proof of the enduring capacity of *Salmonidæ* ova.

AT a recent meeting of the Paris Biological Society, M. L. Vaillant offered some remarks concerning the way in which *Antennarius marmoratus*, a curious fish already studied by Agassiz, builds its nest. Each nest is made of one sea-weed (of the Sargasso Sea) the different twigs being brought together and made fast to each other by the fish by means of a pasty sort of substance provided by the animal itself. Agassiz thought that separate bits of sea-weed were used, but it is shown that it uses the whole of the twigs and branches of a single plant; which, of course, allows of much easier work.

THAT the weasel (*Mustela vulgaris*) destroys frogs is proved by the following incident. While standing near a pond on his estate, a gentleman at Worcester observed a weasel give chase to a frog, which it followed to the water and succeeded in capturing. Holding it firmly by the head, the weasel emerged from the water and brought its victim to the bank, but on finding

itself disturbed let go the frog and disappeared. Happening to visit the spot on the succeeding day the gentleman found the frog alive in exactly the same place where it had been left by the weasel, although it had been bitten through to the skull.

AT a recent meeting of the Jena Naturalists' Society, Herr Stahl read a paper on the significance of those excreta of plants known as *raphides*, *i.e.* crystalline needles often met with in the cells in large quantity. From experiments he inferred that they were a protection to plants against being eaten by animals. Many animals avoid plants with raphides, or eat them reluctantly; and some animals, *e.g.* snail species, in eating plants that have raphides select those parts that are without the crystals. Many plants held for poisonous, *e.g. Arum maculatum*, owe their burning taste simply to the very numerous raphides, which, forced out of their cells, enter the tongue and palate. The juice obtained by filtration has quite a mild taste.

WE have received the Proceedings of the Academy of Natural Sciences of Philadelphia, Part 2, April to August 1887. The volume contains a valuable paper, by Mr. Edward Potts, presenting "Contributions towards a Synopsis of the American Forms of Fresh-water Sponges, with descriptions of those named by other authors, and from all parts of the world." In closing this monograph, Mr. Potts says he knows of no more hopeful field of labour for a young American naturalist, seeking for new worlds to conquer, than that provided by the fresh-water sponges. Active workers in this field in North America have, thus far, but glanced at a few streams and lakes, mostly in the neighbourhoods of Buffalo, Chicago, and Philadelphia, and in parts of Florida, Nova Scotia, and Newfoundland. Mr. Potts has little doubt that the rest of the American continent holds many rare prizes in trust for younger and better-equipped explorers.

ANOTHER important paper by Dr. B. Franke, of Leipzig, upon the preparation and constitution of the hydrates of manganic oxide and peroxide is contributed to the current number of the *Journal für Praktische Chemie*. By the action of 100 c.c. concentrated sulphuric acid upon 8 grammes potassium permanganate, a beautiful dark reddish-brown crystalline salt was obtained of the composition $Mn_2(SO_4)_3 . H_2SO_4 . 4H_2O$. When the crystals of this salt were placed in a solution of soda, they were decomposed with deposition of a crystalline powder. These precipitated minute crystals were found to consist of the hydrate of manganic oxide, $Mn_2O_3 . H_2O$, and were shown to possess the constitution $Mn\langle{}^{O}_{O}\rangle Mn\langle{}^{OH}_{OH}$; they were of a steel-gray colour, and possessed metallic lustre. On heating to a temperature exceeding 120°, water was evolved, and black Mn_2O_3 remained. When, however, the reddish-brown salt was dissolved in dilute sulphuric acid, a precipitate afterwards separated out, consisting of pure manganous acid, $MnO_2 . H_2O$, of constitution ${}^{HO}_{HO}\rangle MnO$. On rapidly filtering and washing with water, alcohol, and ether, the acid was obtained as a brown powder, which on ignition became transformed into black Mn_2O_3. One of the most interesting results of similar experiments with hydrochloric acid, which behaves in a precisely analogous manner, is that they throw considerable light upon the mode of action of hydrochloric acid upon manganese dioxide, the reaction so commonly employed for the preparation of chlorine. The first action is shown to consist in the formation of a chlorine substitution-product of manganous acid, thus: $MnO_2 + 6HCl = H_2MnCl_6 + 2H_2O$. This substance is, however, rapidly broken up into manganous chloride, hydrochloric acid, and free chlorine: $H_2MnCl_6 = Cl_2 + MnCl_2 + 2HCl$. A secondary action then commences, the manganous chloride thus formed combines with further quantities of the chlorine substitution-product to form manganic chloride: $MnCl_2 + H_2MnCl_6 = Mn_2Cl_6 + 2HCl$. The manganic chloride, as is well known, does not remain as such, and Dr. Franke shows that, like the sulphate, it is at once decomposed by water as follows: $Mn_2Cl_6 + 4H_2O = Mn_2O_3 . H_2O + 6HCl$. Finally, the free hydrochloric acid decomposes the crystalline hydrate with formation of stable manganous chloride. It is especially important to have this reaction thus thoroughly cleared up, as it is one of the earliest brought to the attention of students.

A NEW method of determining the amount of fusel oil in spirituous liquors, by counting drops from an instrument named a *stalagmometer*, has been lately brought before the Berlin Chemical Society by Herr Traube, who had previously worked out such determinations with a capillarimeter, but finds the new plan preferable on some accounts. The instrument is a short, bent glass tube bulged at one part, into which the liquor is sucked up, being previously diluted to about 20 vols. per cent. The room-temperature being noted, the number of drops in a given volume is counted, and then compared with the corresponding number got at the same temperature from pure 20 per cent. alcohol. A plus of about 1·6 drop per cent. in the former case indicates about 0·1 per cent. fusel oil; one of about 3·5 drops 0·2 per cent. fusel oil, and so on. Even 0·05 per cent. can be certainly determined, and, while the author considers this arrangement quite sufficient for practice, he describes an improved form of his method which admits of determining 0·02 per cent. fusel oil, as well as etheric oils, &c. In this the fusel oil is first expelled from its solution by means of certain salts.

IN a recent series of experiments on the resistance of materials to frost, Herr Blümcke took the method of putting cubes of various kinds of stone in distilled water, under the receiver of an air-pump, and after the air was exhausted and the cube saturated with liquid, exposing the latter to a freezing mixture. He finds that a material is more resistant the less the weight of particles it loses in a given number of freezings. The results corresponded pretty much to experience. Besides the well-known visible phenomena of weathering, there is, even in the first action of frost, a loss of extremely fine particles, not perceptible in the material itself. The appearance of the visible phenomena occurs sooner the more water the stone has taken up. The mode of working has a not unimportant influence on the resistance of materials.

AT the monthly meeting of the Linnean Society of New South Wales, held October 26, Dr. Oscar Katz read a paper on three new kinds of phosphorescent Bacteria, in addition to three already recorded by the author at the meeting of last June: (1) *Bacillus argenteo-phosphorescens liquefaciens*, obtained from sea-water at Bondi; its cultures, liquefying gelatine, emit in the dark a silvery light, which, however, is the weakest of the six kinds hitherto found; (2) *Bacillus argenteo-phosphorescens* II., derived from a luminous piece of a small squid (*Loligo*), and, at the same time, from luminous pieces of the Sydney Garfish (*Hemirhamphus intermedius*, Cant., *H. melanochir*, Cuv. and Val.); (3) *Bacillus argenteo-phosphorescens* III., from the squid already mentioned. Neither of the latter micro-organisms causes liquefaction of the gelatine. They give off in the dark a handsome silver light, much more intense than that of the first-mentioned, but resembling that of the previously-exhibited *Bacillus argenteo-phosphorescens* (now to be designated I.). From this latter Nos. II. and III. distinctly differ. Fuller details about all these luminous Bacteria will be forthcoming shortly.

DURING his last journey to the Amdo, M. Potanin discovered an interesting manuscript containing a Tibetan version of the Mongolian epics of Hesser-Khan. Speaking of this discovery, Prof. Vasilieff has lately expressed his belief that travellers might, if they tried, find many valuable manuscripts in Eastern Turkistan

—relics of the earlier Buddhist era and of the Chinese dominion. Such treasures are probably also to be found in Japan and Corea. It is known that there are Japanese versions of Hiuan Thsang's journey; and Prof. Vasilieff has been informed that manuscripts written on palm-leaves, and brought from India, have been seen in Corea. Many Coreans formerly visited India as Buddhist pilgrims.

A LIST of publications issued by the authority of the Department of Science and Art has just been published. It includes publications specially relating to instruction in science and art, publications relating to the South Kensington Museum, catalogues of reproductions and of loan collections, miscellaneous publications, hand-books, books of photographs, and diagrams.

MESSRS. GIARD AND BONNIER have just published a valuable memoir on the anatomy of the Bopyridæ, with good illustrations.

WHALES—the so-called "herring" whales, which follow the shoals of that fish—are very numerous off the west coast of Norway this winter, and large catches have been made.

IN the Report of a Committee appointed by the British Association "for the purpose of investigating . . . the quantity and character of the water supplied to various towns and districts" from the permeable formations of England, a very misleading statement as to the character of the water-supply of Cheltenham was made. In a later Report of the same Committee, just issued, the error is frankly admitted. "In the Eleventh Report of your Committee," we read, "by a most unfortunate misprint, the reservoirs are described as 'dry' during the drought of 1884, instead of 'short,' as reported by a correspondent, in which statement he was obviously incorrect. Your Committee much regret that the condition of the Cheltenham Waterworks should have been misrepresented by them, as they were fully aware of the ample supply and pure quality given to the town by the Corporation, the purity of which has been testified to by Drs. Allen Miller, Frankland, Way, and Tidy, and Prof. Voelcker."

THE *Brighton Herald* says it is expected that the medallion portrait of the late Dr. Thomas Davidson, F.R.S., Gold Medallist of the Royal Society, Wollaston Medallist of the Geological Society, and first Chairman of the Brighton Museum Committee, executed in marble for the Committee of the Davidson Memorial by Mr. Thomas Brock, A.R.A., will be unveiled early in the new year. The work is said to be an excellent likeness.

A SHOCK of earthquake was reported from Oberhausen on December 9. The direction was from west to east.

LAST week Sir John Lubbock delivered an interesting address in Queen Street Hall, Edinburgh, to the members of the Edinburgh Philosophical Institution on "The Sense and Senses of Animals." He said one would gratefully admit that the dog was a loyal and true and affectionate friend, but when we came to consider the nature of the animal our knowledge was very limited. That arose a good deal from the fact that people had tried rather to teach animals than to learn from them. It had occurred to him that some such method as that which was followed in the case of deaf-mutes might prove instructive if adapted to the case of dogs. He had tried with a black poodle belonging to himself. He then went on to relate several experiments he had made with pieces of cardboard with different words marked upon them. He had taken two pieces of card, one blank and the other with the word "food" upon it. He had put the latter on a saucer containing some bread and milk, and the blank card he put on an empty saucer. The dog was not allowed to eat until it brought the proper card to him. This experiment was repeated over and over again, and in about ten days the dog began to distinguish the card with the letters on it from the plain card. It took a longer time to make the dog realize the difference between different words. In order to try and discover whether the dog could distinguish colours, he prepared six cards, marking two of them blue, two yellow, and two orange. He put one of each on the floor, and tried to get the dog to bring to him a card with the same colour as one which he showed the dog in his hand. After trying this for three months, he found that his experiment in this direction was a failure. He had always felt a great longing to know how the world appeared to the lower animals. It was still a doubtful point whether ants were able to hear. From experiments which he had made, he had come to the conclusion they had not the power of addressing each other. His impression on the whole was that bees and ants were not deaf, but that they heard sounds so shrill as to be beyond our hearing. There was no doubt about insects seeing. He related several experiments he had made with the view of discovering whether different insects could distinguish different colours and had any preference for particular colours. The colours of objects produce upon insects an impression very different from that produced on human beings. The world to them might be full of music which we could not hear, colours which we could not see, and sensations which we could not feel.

THE additions to the Zoological Society's Gardens during the past week include a White-crested Guan (*Pipile jacutinga*) from Guiana, presented by Captain J. Smith, s.s. *Godiva*; two Silky Bower Birds (*Ptilonorhynchus violaceus*) from New South Wales, deposited; two Viscachas (*Lagostomus trichodactylus*) born in the Gardens.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *JANUARY* 1–7.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 1

Sun rises, 8h. 8m.; souths, 12h. 3m. 39·5s.; sets, 15h. 59m.: right asc. on meridian, 18h. 46·0m.; decl. 23° 2′ S. Sidereal Time at Sunset, 22h. 42m.

Moon (at Last Quarter on January 6, 12h.) rises, 17h. 29m.*; souths, 1h. 31m.; sets, 9h. 25m.: right asc. on meridian, 8h. 12·0m.; decl. 19° 10′ N.

GEOGRAPHICAL NOTES.

THE two great medals of the Paris Geographical Society have been awarded to General Alexis de Tillo for his great topographical work on Europe and Asia, and to M. Alphaud, Inspector-General of the Ponts et Chausées, who, "by inspiring a feeling for the beautiful and of the necessities of hygiene, has done so much to improve the topography of the capital." Medals of the first class were awarded to M. Enguehard, geographical draughtsman; Prof. François Bazin; Prof. Maxime Mabire; Prof. Paul Gaffarel, for a work on the soil of France; M. Fauve, for his fine topographical works; M. Ch. Lasalle, for a work on the defences of France; M. Pierre Collet, for his relief plans; Lieut. Somprou; M. Poinet; and M. Verragen.

LIEUT. VON FRANÇOIS and Dr. Wolf will start shortly on a scientific mission to Togoland, one of the German possessions on the West Coast of Africa.

IN the new part of the Journal of the Manchester Geographical Society there is an instructive paper by the Rev. R. P. Ashe on Uganda, and the manners and customs of its people.

NEWS from Africa states that the well-known African traveller, Herr Gottlob Adolf Krause, has returned to Accra on the Gold Coast. In May 1886 he commenced his exploring expedition. Starting from Accra and crossing the River Acropang-Volta at Kpang, he proceeded in an easterly direction, passing through Kpando, Krahje, Salaga, Dagomba, Walawala, East Gurunsi, and Busanga to Wagaduga and Ban Djagara, penetrating to within a few miles of Timbuctoo. On his return he journeyed through West Gurunsi, the Ashantee District, Kintimso, Salaga, Sogede, Baleta, Gheshi, Atakpama, and Pla. Lieut. Kund on his journey to Cameroon met Herr Krause at Accra, and sends this report. Herr Krause states that to the north of Salaga the influence of the Sahara is most prominent, and the country is more desolate the further north one goes. Rice and tobacco are universally cultivated. The principal articles of commerce are kola-nuts and salt, the district being chiefly inhabited by the Fula tribe. Nearer to the coast there are several other tribes and dialects, but the Haussa language is most generally spoken. Most of the population is still heathen, but some of the merchants and better educated families are Mohammedans. Herr Krause was not enabled to proceed as far as Timbuctoo, owing to the unfriendliness of the Sheikh Tidchani.

THE *Bollettino* of the Italian Geographical Society for October and November publishes a valuable paper by Sig. A. Borda on the geography, history, and present social conditions of the Republic of Columbia (New Grenada), which promises to enter on an era of peace and prosperity under its enlightened and popular President Nunez, who was elected last June for a term of six years. The present population is calculated on official returns at about four millions, including 200,000 still living in the tribal state in the more inaccessible forest regions. These forests are described as abounding in a great variety of valuable trees yielding the finest cabinet woods, balsams, gums, dyewoods, alimentary and medicinal products. The flora and fauna are scarcely exceeded by those of any other land in diversity of types, while the country contains vast supplies of minerals, such as gold, silver, platina, rubies, emeralds, crystals, porphyry, salt, and sulphur. Since the conquest till the present time the yield of the precious metals is estimated at £130,000,000, mined chiefly in the departments of Canea and Antioquia. Mining operations, which had suffered much from the unsettled state of the country, have recently received a fresh stimulus by the introduction of foreign capital and improved engineering appliances. The metalliferous districts, which occur at various elevations, and especially along the river valleys, are stated to be generally salubrious, and foreigners are now enabled to purchase mines on the same terms as the natives. But the great natural resources of Columbia still lie almost untouched, chiefly through the lack of good and regular communications, the roads being generally impracticable for wheeled traffic, while the railway system is little developed. Besides the Panama, Bolivar, and Cucuta lines already open, others are in course of construction in the departments of Canea, Antioquia, Cundinamasca, Tolima, and Santander. The great water highway of the Maddalena has a fleet of twenty-five steamers, and is connected with the seaport of Cartagena by the Digue, a navigable canal branching off at Calamar. The yearly imports from Europe and the United States average £3,000,000, and the exports £1,600,000. The revenue for 1887–88 is estimated at £4,000,000, the expenditure £4,600,000, and the public debt £4,500,000, half internal and half foreign. The Government has still at its disposal extensive domains, which are granted on favourable terms to immigrants as well as to native and foreign speculators. At present the country is in the enjoyment of profound peace, with improved external and internal relations, and a general desire to close once for all the era of aimless political revolutions.

JOURNAL OF THE ROYAL AGRICULTURAL SOCIETY.[1]

THE most recent number of this Journal well keeps up the credit of its predecessors in spite of the grievous loss the Society sustained a year ago in the death of its talented editor, Mr. H. M. Jenkins. The contributors include the Earl of Coventry, Sir F. Bramwell, F.R.S., Drs. J. Voelcker and P. Vieth, Major Craigie, Principal W. Robertson of the Royal Veterinary College, Mr. James Macdonald, of Edinburgh, Messrs. Bernard Dyer, Albert Pell, Charles Whitehead, William C. Little, Charles Clay, Herbert J. Little, and others. Since these remarks were penned, we regret to hear of the sudden death of Principal Robertson, of the Royal Veterinary College.

The contents may be classified as—strictly agricultural, comprising articles on ensilage, sheep-feeding experiments, and reports on the prize-farm competitions in Northumberland; statistical, as presented in papers upon twenty years' changes in our foreign meat supply; engineering, as represented in trials of portable engines, and report of the consulting engineers at Newcastle; and purely scientific, as in papers on micro-organisms and their action on milk and milk products, on protective inoculation for anthrax and quarter ill, and on the progress of the Hessian fly.

Few of the papers possess such a wide general interest, both scientific and sanitary, as that of Dr. P. Vieth, on the action of micro-organisms on milk. Milk is subject to *lactic* fermentation, caused by the presence of a bacillus, consisting of short motionless rods propagating by segmentation. The effect of these bacilli is to cause the milk to sour and lose its liquid character, and assume the appearance of a gelatinous mass. The milk, in fact, "turns," and a separation of the curd from the whey follows, as though rennet had been added, but from a different cause. It is also now shown that lactic fermentation requires to be induced by the introduction of bacilli from without, after the milk is drawn from the cow, and that it is not inherent

[1] "Journal of the Royal Agricultural Society," Series II. vol. xxiii. Part II., 1887. (John Murray, Albemarle Street.)

in the milk. Lactic fermentation cannot take place unless in the presence of free oxygen, and at temperatures ranging from 50° to 114° F. Below and above these limits the process is arrested. The *butyric* fermentation is caused by a bacillus of larger size than that to which lactic fermentation is due, and occurs in milk free from lactic acid and of alkaline reaction. The bacillus of butyric fermentation will withstand a higher degree of heat, and the spores will stand a boiling heat for five minutes very well. *Alcoholic* fermentation is induced in milk which has already passed through the stage of lactic fermentation by means of a special ferment which has been used from time immemorial in the Caucasus under the name of kephir. By the action of this ferment a preparation similar, if not identical with koumiss is produced. *Slimy* fermentation gives what is known in Norway as ropy milk, where it is used as an article of diet. With this fermentation a micro-organism is also associated. Cheese is a product of fermentation from beginning to end. Not only is it a fermentative process by which the curd is separated from the whey, but the processes of ripening also depend upon various micro-organisms. It is generally thought that the differences between the cheese made in various localities, and which so well evade imitation, are due in a measure at least to the propagation and prevalence of micro-organisms of a sort which may be rare or wanting in other districts; and that consequently it may be easy to make cheese of a particular flavour or character in one district which it will be found impossible to produce in another district.

The able paper by Major Craigie, on twenty years' changes in our foreign meat supply, is well worth reading. The paper is deeply interesting to agriculturists, and deals with the probable sources of animal food for the constantly increasing human family. The enormous increase of population in the United States of America is especially noticed, and the following extract from the Commissioner of Agriculture's (Mr. Colman's) address to the "Cattle Kings" assembled at Chicago is significant and hopeful for the future of agriculturists:—"In 1880 we had 50,000,000 of inhabitants; in 1905 we should have 100,000,000; in 1930, 200,000,000; in 1955, 400,000,000; in 1980, less than 100 years hence, 800,000,000 of inhabitants. Where are these teeming millions to live? On what are they to subsist? Where and how are the cattle to be bred and reared that must be relied upon to furnish beef?" In answer to all of which questions we may be permitted to point out that many disturbing causes may operate to check this uniform future development of the population of the States. The wonderful results of geometrical progression have often astonished schoolboys; and as naturalists we also know what *ought to* happen in the case of insects, or even of mammals, if their actual increase in the least degree corresponded with their natural powers of expansion. Even the human family does not always increase as rapidly as it might. Stress is laid upon the fact that most of the available land for cattle-ranching has already been laid hold of, and that further extension of this industry has for the present received a check from which it is not likely to recover. Also the singular diminution in the numbers of sheep throughout the Old World, and the less noticed fact that since 1883 the sheep stock of the United States has lost 6,000,000, must bear upon the price of mutton sooner or later. In the United Kingdom, including islands, we had in 1867 111 sheep to every 100 inhabitants; in 1887 we have 79. In France they had in 1867 80 sheep to every 100 inhabitants, but in 1887 they only have 59. The same story is told in every European country without exception, and the sheep population of the world would have most disastrously decreased had it not been for the large increase in stocks in the Australasian colonies and the Argentine Republic.

The experiments upon ensilage are particularly worthy of attention. The process of ensilage has its devotees, who, like Prof. Rogers, consider it to be a panacea for agricultural distress. This sanguine view has been supported by the experience of many agriculturists, who have not the least doubt as to the superiority of silage over hay, and who also look upon the peculiar succulence of silage as a fact of great importance. One thing, however, appears certain—that, valuable as ensilage may be, it cannot equal in nutrient properties young growing grass. Hay or silage may be of more value in winter than is grass in summer, but intrinsically grass is that perfect product of unaided Nature which no art can better.

An optimist view thus stated may be challenged, and the propounder asked if the fresh clusters of the grape are equal to the ripened vintage wine? The matter requires to be dealt with scientifically, and it is with a view to clearing up the matter that the Royal Agricultural Society has with the aid and concurrence of the Duke of Bedford carried out a series of crucial experiments upon the value of ensilage as a stock food in comparison with the value of hay. Such an experiment is liable to many sources of error. The Wilmington experiments of 1886 abounded in them. There was no guarantee that the hay as hay was as good as the silage as silage. There was no record as to the comparative areas of land required to produce the hay or the silage. The large amount of silage eaten by the bullocks bore an unsatisfactory relation to the small quantity of hay eaten, indicating that the ensilage was good and palatable, while the hay was unpalatable. This inference is borne out by the *dictum* of the Society's chemist, that the hay at Wilmington was "very inferior indeed," while the silage "was really well made." Such sources of error invalidate the results obtained, and if, as was the case, the cattle fed on good silage did better than those fed on bad hay, all we can say is that no other result could very well have been expected. At Woburn the experiments were more strictly conditioned. "5½ acres of ground were carefully measured out, and the grass was only cut as it was wanted for carting to the silo, not being allowed to lie on the field any length of time. Two carts going side by side were filled simultaneously, and then taken to be weighed. After weighing, one cart went to the silo, into which grass was to be filled, and the other went to a meadow, where the grass was spread and left for haying." I must not take up space by explaining the complete system of sampling the grass, and the two products of hay and silage. Suffice it to say that the utmost pains was taken to obtain thoroughly representative samples for purposes of analysis. The hay and silage thus obtained might be considered as strictly comparable with one another, and if the process of silage is preferable to the older and more fragrant system of hay-making, the comparison might here be instituted with every prospect of deciding the question. The experiment was made upon twelve Hereford steers, six of which were placed on a diet of 3 lbs. of cotton cake, 5 lbs. of maize meal, with hay *ad libitum* and water *ad libitum*. The other six were given 3 lbs. of cotton cake, 5 lbs. of maize meal, with silage *ad libitum*, and water *ad libitum*. The conditions were the same except with regard to the hay and the silage. The bullocks were practically of equal size and weight, although the six bullocks which were placed on the ensilage side of the experiment had the advantage of 9 lbs. over the hay-fed lot, and weighed 60 cwt. 1 qr. 20 lbs. The result after thirty days' feeding was that the hay-fed bullocks had increased more in weight, the comparative merits of the two systems of feeding being as follows:—

Gain per day per head of bullocks receiving			hay .	2·3 lbs.
Ditto	ditto	ditto	silage .	2·1 lbs.

During the succeeding month the result was in favour of the ensilage, but in the total period of 84 days, which terminated on March 10, 1887, the result was:—

Gain of hay-fed bullocks		. .	1·96 lbs. per day.
Ditto	silage	ditto . . .	1·98 lbs. ditto.

A very curious result was arrived at with reference to the relative amounts of hay and water and of silage and water consumed during this period. The six bullocks receiving hay consumed of hay 20·3 lbs. per head per day, and drank 70·7 lbs. of water, or a total of hay and water of 91 lbs. each. The six bullocks receiving silage consumed of silage 51 lbs. and of water 40·1 lbs., or a total of 91 lbs. each. This very closely accordant result appears to point to the conclusion that the only difference between hay and silage is water, and that hay with plenty of water is quite as good a food for fattening bullocks as silage with less water.

The progress of the Hessian fly is a topic of considerable public interest, and no one could more satisfactorily enlighten us on the subject than Mr. Charles Whitehead. We are told by this excellent practical entomologist that the Hessian fly appeared first in America in 1779, and that a great scare prevailed in England at that time, which turned out to be unfounded. The nearest country to us at present affected with the pest is Russia, which appeared to first receive this unwelcome visitant in 1879, and it is still a moot point whether our Hessian flies have arrived from America or from Russia. That we have it rather bad is plain from the fact that the insect has been proved present in twenty English counties. The theatre of its operations is likely

to be extended during next summer, and we shall probably soon have the satisfaction of knowing whether our climate is suitable to its tastes. If so, it will probably obey the mandate of increasing and multiplying; but its tendency will be towards deplenishing rather than replenishing the earth. The prospect is not exactly nice, but we may take some comfort from Prof. Riley's expressed opinion that the Hessian fly will not prove a very serious plague to British agriculturists.

Downton, December 10. JOHN WRIGHTSON.

THE REPRODUCTIVE ORGANS OF ALCYONIDIUM GELATINOSUM.

IN some specimens of the Polyzoon *Alcyonidium gelatinosum* dredged last summer, I noticed that the colony, in place of being nearly homogeneous in colour and semi-translucent, as is usually the case, had a blotched appearance, caused by the presence of a number of small rounded spots of an opaque grayish-white or pale yellow colour. These average about 0·5 mm. in diameter, and are scattered irregularly through the colony. On teasing up a small part in sea-water, and on making a few rough sections of the living colony, I found that the opaque spots were cavities filled with fully developed active spermatozoa. No ova were visible in the polypides of any of the parts examined, so these colonies were evidently in the condition of sexually mature males. It at once occurred to me that this species of *Alcyonidium* might be unisexual—some colonies male and others female—the males being distinguishable when mature by their spotted appearance. The specimens were preserved for future examination.

On returning to Liverpool, and looking up the literature of the subject, I find that Hincks states ("British Marine Polyzoa," introduction, p. lxxxvi.) that "*Alcyonidium gelatinosum*, according to Kölliker, is unisexual," and I gather from the context that it is the individual polypides that are unisexual, and not the whole colony. Hincks, however, does not give a reference to any paper by Kölliker, and I have not been able to find in the literature of the Polyzoa, or in the bibliographies I have consulted, any paper of Kölliker's which would be likely to contain observations on the reproduction of *Alcyonidium*; therefore I am still uncertain how far Kölliker's remark is intended to apply—to the whole colony, or only to the individual polypides. I know of no other investigations on the subject.

I have now examined a number of thin sections, of both the spotted colonies (including the one formerly dissected) and the usual translucent ones, and I find:—

(1) In the spotted colonies there are a number of greatly distended polypides, with their cœloms filled with fully developed spermatozoa. There are also a few ordinary large, but not distended, polypides, containing each a few young ova.

(2) In the ordinary clear colonies there are neither ova nor spermatozoa to be found.

It is evident, then, that the *colony* is hermaphrodite, whatever the polypide may be. But it is also evident that the spotted colonies are virtually males. Their spermatozoa are fully developed, while their ova are still quite immature. Probably, then, *Alcyonidium gelatinosum* is, like many of the Compound Ascidians, an hermaphrodite in which the reproductive systems arrive at maturity at different times in the life-history. Most of the Compound Ascidians in which I have found this the case are proterogynous (the female organs maturing first), but *Alcyonidium gelatinosum* appears to be proterandrous. If the polypides are unisexual, then the proterandry refers only to the colony as a whole, but it is possible that each polypide may be a proterandrous hermaphrodite, developing ova after it has got rid of the spermatozoa. I hope to investigate this matter further by keeping some colonies alive at the Puffin Island Biological Station, and examining their condition from time to time.

In *Alcyonidium gelatinosum* both the ova and the spermatozoa occur in ordinary polypides, and not, as Hincks states is the case in the closely related species *A. mytili*, in "gonœcia" (cells containing no polypides). In my sections the alimentary canal and tentacles are found cut across here and there in the masses of spermatozoa. The large cavities containing the spermatozoa are evidently ordinary polypides, with the cœlom greatly distended.

W. A. HERDMAN.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 15.—"Note on the Development of Feeble Currents by purely Physical Action, and on the Oxidation under Voltaic Influences of Metals not ordinarily regarded as spontaneously oxidizable." By Dr. C. R. Alder Wright, F.R.S., and C. Thompson, F.C.S.

The authors have noticed that if two or more different kinds of aëration plates be set up on the surface of the fluid contained in a shallow basin in which the oxidizable metal is immersed, and sufficient time be allowed to elapse to enable the films of air attracted to the aëration plates to attain a condition of equilibrium, different constant values are usually obtained for the E.M.F.'s generated by opposing to the oxidizable metal first one and then the other of any given pair of aëration plates, the currents generated being rendered throughout of too small density for "running down" to take place during the observations by interposing a large resistance in the circuit. If when this state of constancy has been attained the two aëration plates be opposed to each other with a considerable resistance in circuit, a current passes from the one giving the higher value when opposed to the oxidizable plate through the external circuit to the other; this current at first is of such magnitude as to correspond exactly with the E.M.F. due to the difference between the E.M.F.'s exhibited when the two plates respectively are opposed to the oxidizable metal; but after some time it gradually diminishes; even after several days, or even weeks, however, it is usually still measurable; and if a miniature silver voltameter be included in the circuit, in many cases an appreciable amount of crystalline silver is found to be slowly deposited on the negative electrode of the voltameter, which may conveniently be a thin gold wire immersed to a depth of a few millimetres in silver-nitrate solution, a silver plate or wire forming the positive electrode. Various experiments are described in illustration.

It is obvious that during the passage of a current the dilute sulphuric acid between the two plates must be electrolysed, so that hydrogen would tend to be liberated on the surface of the plate acquiring the higher potential, and oxygen on that of the other; the hydrogen whilst nascent would necessarily be more or less completely oxidized to water by the oxygen of the film of condensed air; so that on the whole the net chemical action in the cell itself would be either *nil* (if all hydrogen were so re-oxidized) or one *absorbing* heat (if some of the hydrogen escaped oxidation). The oxygen slowly evolved would escape as such, being dissolved by the surrounding fluid. The effect of this should accordingly be that the efficiency of the air-film on the first plate would be more or less depreciated, and that on the second exalted; in point of fact, if the two aëration plates in such an arrangement which has been generating a current for some time be (by means of an appropriate switch) disconnected from one another and successively opposed to a given oxidizable plate, the one does give a considerably lower and the other usually an appreciably higher value than the constant ones previously obtained (before the two aëration plates were directly opposed to one another) on opposing each severally to the oxidizable metal; whilst on allowing the cell to stand for some time generating no current, the lower value gradually rises and the raised one falls until sensibly the old constant values are again obtained.

When *silver* plates are used in conjunction with a fluid capable of dissolving silver oxide (such as dilute sulphuric or acetic acid or ammonia solution), distinctly larger amounts of current are usually developed than with platinum or gold plates, and simultaneously silver passes into solution, the plate acquiring the lower potential diminishing in weight, and, in short, behaving precisely as though it were an oxidizable metal, such as zinc or copper. Obviously this is due to the circumstance that with silver the ion liberated attacks the metal of the plate acquiring the lower potential; but the remarkable part of the action is that this attack is only partial, so that the amount of silver dissolved is invariably *less than that equivalent to the current passing*, *i.e.* less than that deposited in a silver voltameter included in the circuit.

Various illustrative experiments are described which show that the difference between the silver dissolved and that deposited by the current is relatively much larger with the weakest currents.

It is obvious that if silver will dissolve in acids, &c., under the comparatively feeble oxidizing influence of an aëration plate,

much more rapid solution might be anticipated by substituting for such a plate platinum immersed in a powerfully oxidizing fluid such as strong nitric acid, or sulphuric acid solution of chromic anhydride. In point of fact, the authors have found that on setting up such cells where the silver was immersed in dilute sulphuric acid (*i.e.* Grove's cell with silver instead of zinc, and so on), electromotors of notable power are produced, at any rate until the silver plate becomes coated with sparingly soluble sulphate. Even in these cases, however, perfect correspondence between the amount of silver dissolved and that deposited in a voltameter included in the circuit does not subsist, the latter being always measurably the greater.

Just as silver is capable of being dissolved in an appropriate fluid when opposed to an aëration plate, so may several other metals not ordinarily prone to atmospheric oxidation; thus mercury with dilute sulphuric acid as fluid, and an aëration plate of platinum sponge, generates a measurable continuous current, forming *mercurous sulphate* in so doing, so that after some time the liquid becomes turbid through separation of that sparingly soluble salt, and the filtered fluid precipitates calomel on addition of dilute hydrochloric acid. Acetic acid acts similarly, but far less energetically. Potassium cyanide solution, on the other hand, causes a much more rapid solution of mercury, forming *mercuric potassiocyanide;* it is noticeable that in this case only 100 parts of mercury go into solution for 108 of silver deposited in the voltameter, whereas when sulphuric acid is used 200 parts of mercury become sulphate per 108 of silver deposited.

If gold be substituted for mercury in this latter arrangement, rapid solution takes place with formation of *aurocyanide of potassium*, 196 parts of gold being dissolved per 108 of silver thrown down in the voltameter. Palladium behaves precisely as gold, 52 parts of metal being dissolved per 108 of silver deposited; local action sometimes causes in each case a slight *excess* of amount dissolved relatively to the current passing, the opposite result to that observed with the silver cells above described.

Of course, if more powerful oxidizing agents are used than simple aëration plates (such as platinum in sulphuric-chromic solution) the action goes on in all such cases still more rapidly.

"On the Functions of the Occipital and Temporal Lobes of the Monkey's Brain." By Dr. Sanger Brown and Prof. E. A. Schäfer, F.R.S.

The authors gave an account of experiments upon the brain of monkeys, involving the removal of the occipital and temporal lobes respectively. These experiments show that removal of the whole of one occipital lobe produces permanent hemiopia, and that removal of both occipital lobes produces complete and permanent blindness of both eyes; and, further, that for the production of these effects it is not necessary that the angular gyrus should be involved in the lesion.

They also show that not only the superior temporal gyrus but even the whole temporo-sphenoidal lobe can be removed on both sides of the brain in monkeys without producing any appreciable permanent effect on hearing.

The reading of the paper was illustrated by diagrams exhibiting the extent of the lesions, as well as by casts of the brains.

Royal Meteorological Society, December 21.—Mr. W. Ellis, President, in the chair.—The following papers were read:—The mean temperature of the air at Greenwich, from September 1811 to June 1856, by Mr. H. S. Eaton. This is a discussion of the meteorological journals of the late Mr. J. H. Belville, and those of the Royal Observatory. The general results of this investigation are:—(1) That there was no appreciable change in the mean annual temperature of the air at Greenwich in the period 1812 to 1855 inclusive. (2) That on the eminence on which the Royal Observatory is situated the average temperature at night, or rather the early morning, is in all cases higher than over the lower grounds. (3) That with a north-wall, or possibly a north-window exposure, higher maximum temperatures are found at the lower stations. (4) That the movements of the thermometer are retarded with a north-wall exposure as compared with an instrument on an open stand, especially where the situation is a confined one, the indications of the thermometer not following changes of temperature so promptly owing to the modifying influence of the adjacent building.—Report on the phenological observations for the year 1887, by the Rev. T. A. Preston. The past season was a most exceptional one. For flowers it was disastrous; fruit was generally a failure, though there were exceptions; those kinds which promised well turned out very small or spoilt by insects. Vegetables were universally poor, roots were destroyed by insects or drought, and green crops soon passed off. The wheat crop, however, was better than was expected. Barley on light lands was poor, but that which was sown early was satisfactory. Meadow hay was not up to an average crop, but clover and seed hay were much more nearly so. In Kent the fruit crops turned out lighter than usual, but the prices have ruled higher.—Earth tremors and the wind, by Prof. John Milne, F.R.S. The author has made a detailed examination of the tremor records obtained in Tokio, and compared them with the tri-daily weather maps issued by the Imperial Goverment of Japan. From this comparison the following conclusions have been drawn:—(1) Earth tremors are more frequent with a low barometer than with a high barometer. (2) With a high barometric gradient tremors are almost always observed, but when the gradient is small it is seldom that tremors are visible. (3) The stronger the wind the more likely it is that tremors should be observed. (4) When there has been a strong wind and no tremors the wind has usually been local, of short duration, or else blowing inland from the ocean. (5) When there has been little or no wind in Tokio and yet tremors have been observed, in most cases there has been a strong wind in other parts of Central Japan. (6) From 75 to 80 per cent. of the tremors observed in Tokio may be accounted for on the supposition that they have been produced either by local or distant winds. (7) The only connection between earth tremors and earthquakes in Central Japan is that they are both more frequent about the same season.—Pressure and temperature in cyclones and anticyclones, by Prof. H. A. Hazen. The author has made a comparison of the observations at Burlington and on the summit of Mount Washington, U.S.A., and as the result of a study of about 4000 observations from two days before till two days after the passage of cyclone and anticyclone centres, he has arrived at the following conclusions:—(1) In both cyclones and anticyclones the pressure lags from 10 to 11 hours at the summit of Mount Washington. (2) The temperature change at the base precedes very slightly the pressure change, but at the summit the change occurs nearly 24 hours earlier. (3) The temperature appears to be a very little earlier at the summit than at the base, and certainly varies much more rapidly at the former. (4) In a cyclone the difference in temperature between base and summit is less than the mean before the storm, but the difference rapidly increases after the centre has passed. Just the contrary is true in an anticyclone. (5) The total fall in pressure in a cyclone at the summit very nearly equals that at the base, and likewise the rise in an anticyclone. (6) The fluctuation of temperature—that is, from the highest to the lowest—at the summit is double that at the base in a cyclone; but it is only a little greater in an anticyclone.

EDINBURGH.

Royal Society, December 5.—The Hon. Lord Maclaren, Vice-President, in the chair.—After reading an opening address, the Chairman presented the Victoria Jubilee Prize to Sir W. Thomson, for his contributions to the Society's publications on various subjects in hydrokinetics.—Sir W. Thomson read a paper on Cauchy's and Green's doctrine of extraneous pressure to account for Fresnel's wave-surface. The object of his investigation was to place Green's treatment of the subject on a more satisfactory basis than it had been left by its author.—Sir W. Thomson also exhibited models of the minimal tetrakaidekahedron, a figure which he discusses in the *Philosophical Magazine* for this month.—The second part of a paper on micro-organisms, by Dr. A. B. Griffiths, was communicated by Prof. Crum-Brown.—Prof. Wallace laid on the table a paper on the blackening of the skin of domesticated animals in tropical regions.

PARIS.

Academy of Sciences, December 19.—M. Janssen in the chair.—Generation of algebraic surfaces of any order, by M. de Jonquières. The theorem here demonstrated supplies a fresh instance of the intimate and essential part played by the properties of numbers in several questions of general geometry, and especially in those concerned with the generation of surfaces and curves, as well as with the number of double and multiple points with which the latter may be endowed.—Reply to M. Wolf's communication entitled, "Comparaison des divers systèmes de synchronisation des horloges astronomiques," by

M. A. Cornu. The regulating apparatus introduced into his system of synchronizing clocks by M. Cornu, and objected to by M. Wolf as useless and even inconvenient, is shown to be free from these drawbacks, and in fact indispensable for strict accuracy. To these remarks M. Wolf replies that the system at work at Greenwich for twenty-seven and in Paris for seventeen years dispenses altogether with any such arrangement as that proposed by M. Cornu.—On the cause of the deviation of the arrows indicating the direction of the wind on synoptical charts of cyclones, by M. Faye. This deviation is traced entirely to the friction or resistance of the ground over which the cyclone is moving, and harmonizes in no way with the erroneous hypothesis of ascending cyclones. It is greater on land than at sea, and imperceptible in the case of waterspouts and true tornadoes. It also diminishes with the distance from the centre of the cyclone, disappearing altogether near the central calm.—On the state of the sulphur and phosphorus present in plants, in the ground, and in cultivated soil, and on their quantitative analysis, by MM. Berthelot and André. Having already studied the relations of potassium and nitrogen to the vegetative functions, the authors here deal in the same way with sulphur and phosphorus. The question is treated especially with a view to determining and analyzing the complementary manures best suited for restoring the fertility of exhausted lands.—Note, by M. Albert Gaudry, on the discovery of a gigantic turtle by Dr. Donnezan. This specimen was found, with numerous other fossils, in the Middle Pliocene of Perpignan during the recent excavations connected with the erection of the fortress of Serrat in the Eastern Pyrenees. The carapace, 1·20 metre long, was extracted with great difficulty from the hard rock in which it was completely embedded, the innumerable fragments being carefully put together by Dr. Donnezan, by means of about a thousand brackets. This turtle, which he has named *Testudo perpiniana*, and which he has presented to the Paris Museum, considerably exceeds its living congeners, being equal in size to the *T. grandidier*, a sub-fossil species found in Madagascar. Its survival down to the close of the Middle Pliocene is important for the study of the Glacial period, tending to show that the south of France even then still enjoyed a warm climate.—Experiments with a new hydraulic machine employed for irrigating-purposes, by M. A. de Caligny. By means of this apparatus, which is a modified form of that described by the author in the *Comptes rendus* for December 18, 1882, water with a normal fall of 2·40 metres may be raised to a height of 9·45 metres above the level of the upper stream.—On the degrees of oxidation of chromium and manganese in their fluorescent compounds, by M. Lecoq de Boisbaudran. With a view to solving this question the author describes certain experiments which he has made chiefly with alumina and chromium, gallina and chromium, magnesia and chromium, alumina, potassa, and manganese, lime and manganese; confining himself for the present to a statement of the facts observed.—Elements and ephemeris of the planet Anahita, 270, by M. E. Viennet. By means of the ephemeris deduced from the already published provisional elements the author has been enabled to compare all the observations made down to November 16, and thus determine six normal places for October 12, 15, 18, 21, 27, and November 16. With these fresh elements an ephemeris has been calculated, by which astronomers will be enabled to observe the planet down to the end of the present opposition. The magnitude should then be about 11 or 12.—On the value of the solar parallax deduced from the observations taken by the Brazilian Missions during the transit of Venus in 1882, by M. Cruls. From the reports of the observations made at the three stations of St. Thomas (West Indies), Olinda (Brazil), and Punta-Arenas (Strait of Magellan), the horizontal equatorial parallax of the sun at its mean distance from the earth is found to be $8''\cdot848 - 0''\cdot040 = 8''\cdot808$. The reports are now nearly printed, and copies may soon be expected in Europe.—On the specific heat of tellurium, by M. Ch. Fabre. These experiments show that under its several forms tellurium possesses much about the same specific heat, at least at a temperature of 100° C. or thereabouts. But the differences may possibly increase at higher temperatures, and especially near the point of transformation from amorphous to crystallized tellurium.—Study of a specimen of Welsh coal, by MM. Scheurer-Kestner and Meunier-Dolfus. This was a piece of the so-called "Nixom's Navigation," from Glamorgan, which the authors undertook to examine for Mr. Donkin, and which was found to be so pure that it yielded 88 per cent. of hard bright coke, 4·39 of hydrogen, and not more than ·69 of sulphur.—On sidereal evolution, by M. Ch. V. Zenger.

Berlin.

Physiological Society, December 2.—Prof. du Bois Reymond, President, in the chair.—Dr. Salomon spoke on the physiological action of paraxanthin. Since Fisher's researches have thrown light on the chemical constitution of caffein and theobromin, and shown that the former is trimethyl-xanthin, the latter dimethyl-xanthin, experiments on the physiological action of caffein, theobromin, and xanthin have acquired an increased interest. All these substances produce a double effect when given to a frog—namely, one on the central nervous system, and a curious effect on the muscles, which pass into rigor; the three substances exhibit these properties in graduated degree, a fact which is sufficiently explained by the close relationship of their chemical constitution. It hence appeared to the speaker to be a matter of some importance to investigate the physiological action of the two xanthin-derivatives which he had found in urine—namely, paraxanthin and heteroxanthin. From his researches it appears probable that paraxanthin was also a dimethyl-xanthin, that is, an isomer of theobromin; heteroxanthin, on the other hand, had only been obtained in such minute quantities that its chemical constitution could not be determined, but Dr. Salomon suggested that it might be the missing member in the above series of xanthin-derivatives—namely, monomethyl-xanthin. When the somewhat insoluble paraxanthin was administered locally by subcutaneous injection, it produced a stiffness and rigor of the neighbouring muscles: when given in larger doses, some of the animals became sluggish and died, but in many cases they remained uninjured. When given internally, paraxanthin rarely led to any appearance of poisoning, but, when it did, the effect was limited to a stiffening of the fore-limbs and a general sluggishness of the whole animal. Paraxanthin, therefore, exhibited a physiological action analogous to that of the other xanthin-derivatives. Paraxanthin also possesses a distinct action on the respiratory apparatus, since, in all cases in which any effect was produced, the lungs were found to be strongly inflated. He was unable to examine the action of heteroxanthin, from the smallness of the quantity in which it can be obtained.—Dr. Baginski demonstrated the reducing action of certain Bacteria, using, as a reagent, methylene-blue, which becomes colourless by reduction. The Bacteria were obtained from the intestines of healthy cows. Both *Bacterium lactis* and *Bacterium coli* produced a powerful reducing action in pure cultivations, where the nutrient fluid was coloured with methylene-blue; in those places where oxygen had access the blue colour reappeared. A third Bacterium discovered by the speaker exhibited no reducing power.—Prof. Gad explained, on behalf of Mr. Donaldson, the method introduced by Prof. Martin, of the Johns Hopkins University, Baltimore, of isolating the mammalian heart, and of making observations on its activity for several hours, when isolated from the body and connected only with the lungs. The defibrinated blood which flows from the aorta passes into two Mariotte flasks which are in communication with each other, and thence into the right auricle. By means of this arrangement it can be shown that the heart, when separated from all its nerves, works quicker when the temperature of the blood is raised, and slower when it is lowered. An increase of pressure in the aorta was found to be without any effect, whereas an increased venous resistance increases the cardiac activity. It could not be shown that the heart exerts any suctional action during its diastole.

Meteorological Society, December 6.—Prof. von Bezold, President, in the chair.—The President drew attention to Prof. Hann's two most recent publications, namely, the "Atlas of Meteorology" and "The Barometric Pressure in Middle and South Europe according to Observations extending over Thirty Years," and gave a short account of their contents.—Dr. Assmann gave an account of the experiments he has carried on during the last year and a half with a view to determining the true temperature and humidity of the air. After describing the methods previously used to determine the true temperature of the air and his own unsuccessful attempts before he arrived at a satisfactory result, he explained the principle of the thermometers as finally employed, and demonstrated the same by exhibiting several of them. These instruments consist of a fine sensitive mercurial thermometer, of which the small bulb is surrounded by a highly burnished cylinder of nickel-plated brass, open at the lower end.

At the upper end the brass cylinder has a lateral opening by which its interior can be connected with an india-rubber aspirating ball. The chief difficulty met with was in the construction of a suitable valve for the aspirating ball. Finally he succeeded in making a valve such that no air was ever driven back towards the thermometer when the ball was compressed, but only drawn over the bulb of the instrument during the aspiration at the rate of ·2 to 2·5 metres per second. Within these limits the rate at which the air is drawn over the bulb had no influence on the temperature recorded by the thermometer. Of extreme importance, as showing the suitability of the instruments, were the speaker's observations on the temperatures recorded by two of his thermometers, of which one was exposed to the direct rays of the sun, while the other was shaded by a distant shutter: the two thermometers recorded the same temperature, while at the same time an actinometer exposed to the sun showed a temperature 17° C. higher. The same exactness in the determination of the humidity of the air is obtained when a pair of these thermometers is used, and the bulb of one is wrapped round with a piece of moist cloth. This instrument is specially suitable for observations in a balloon. The speaker explained that only shortly before the present meeting he had found that a similar instrument had been constructed by Welsh about the year 1850.—Dr. Robert von Helmholtz gave an account of experiments which he had carried on conjointly with Dr. Sprung with a view to determining the humidity of the air. They had both arrived, independently of each other, at the idea that the determination of the dew-point might best be made, not, as in the usual way, by the condensation on the bulb of a thermometer, but by measurement of the amount of rarefaction which the air must undergo in order that a mist may be produced. In a previous research the speaker, when determining the vapour-tension over solutions of salts, had compressed the air in a closed space, and then obtained a formation of mist by suddenly reducing the pressure again to that of the atmosphere. By determining the general excess of pressure which is thus requisite, the dew-point may be determined. Dr. Sprung has compared the dew-point as thus determined and as obtained by Regnault's apparatus. The experiments are not yet carried sufficiently far to yield any numerical results, but even now it may be said that this new method of determining the dew-point is extremely trustworthy.

Physical Society, December 9.—Prof. du Bois Reymond, President, in the chair.—Dr. Badde developed the mathematical formulæ by means of which he can determine the vibrational condition not only of a vibrating string, but also of a square plate—formulæ which make it possible to determine the relation between the pitch of the note and the vibration-amplitude of the vibrating plate.—Dr. Pringsheim gave an account of the experiments he has made, in conjunction with Dr. Summer, to determine the quotient (k) of the specific heat of gases. The value of k is determined either by measuring the rate of propagation of sound in gases which obey Mariotte's law, or else from the ratio of temperature to pressure when the volume is kept constant. Up to the present time the rate of transmission of sound has not been so exactly determined that the values can be used for deducing the value of k. Similarly the second method has as yet given very discordant results, while at the same time the experiments have not been free from errors. Drs. Pringsheim and Summer have compressed air in a glass balloon whose capacity was sixty litres, and determined its temperature by means of a fine silver wire passing through it whose electrical resistance was known. Hereupon the pressure in the balloon was allowed to sink to that of the atmosphere by opening a tap leading into it, and the cooling thus produced measured by means of the wire. Immediately upon this the tap was again closed, the air becoming warmed by the heat which passed into it from the air surrounding the balloon, and the rise of temperature again measured. During these experiments it was found to be of no consequence whether the rarefaction of the compressed air took place rapidly through a tap with a large bore, or through one with a narrow aperture; the wire always showed the same amount of cooling, thus proving that it follows the alteration of temperature of the air very rapidly. Similarly the length of the wire was found to have no effect on the results, thus showing that the temperature of the surroundings has no influence on the temperature recorded by the wire. The resistance of the wire was determined by the bridge-method, partly by means of a galvanometer, partly by means of a telephone. The ratios of the alterations in resistance of the wire to alterations of temperature were determined, within the necessary limits, for several fine wires. The speakers considered that the only objection which can be raised to their experiments is that the above determination was not made with the same wires which were used in their experiments, and they propose to do away with even this objection by some later experiments which have not as yet been carried out. All other possible objections have been set aside by varying the conditions of their work while obtaining constant results. As a mean of the separate measurements they obtained as a value for k the number 1·384; the deviation for the mean value amounted only to a few hundredths per cent. The above value for k cannot however be taken as being absolute until it has been proved that there is a proportionality between the temperature and resistance of the silver wire which they used in their experiments.

ELECTRICITY FOR PUBLIC SCHOOLS AND COLLEGES.

Electricity for Public Schools and Colleges. By W. Larden, M.A. (London: Longmans, Green, and Co., 1887.)

THIS is a book which possesses many good points, but which becomes, on close acquaintance, painfully disappointing, and even irritating, to the reader. The author has undoubtedly spared no pains to make it full of information; but its very fullness becomes bewildering, owing to the way in which the material is cut up and put together. One might almost imagine that it had been reduced from a much larger work, chiefly by means of deletions, and without the rounding-off of the angularities which such a process would inevitably develop.

The science of electricity and magnetism is, without question, an experimental science; and the author of the present work does not offer his book to his readers as a book on the mathematical side of this experimental science; but as an elementary book suitable for higher schools and for Colleges. He confines himself as to mathematics by assuming "no more mathematical knowledge than is usually possessed by the higher boys in a classical school." Under these conditions we should expect to have a book containing exact and well-finished descriptions of experiments and apparatus, along with explanations of phenomena and with theory brought down to correspond with our present knowledge on this most fascinating subject. Expectations or hopes such as these are very far from being realized in the book before us.

The amount of material collected by the author is undoubtedly very great. The number of instruments and machines referred to and described is enormous. The descriptions are, however, often unsatisfactory, nor are they written with any attempt at finish or good taste The book is supposed to be for the use of well-educated beginners; but we think it would be difficult to find a worse model for boys or young men as to the writing of descriptions of apparatus or of experiments. Often the heading of a paragraph has half the duty to perform; the remainder may be done by a diagram, which is lettered in a tantalizing way, as if a description had been intended.

Here, for example, are the descriptions of two of the most important frictional electric machinés:—

"II. *The Common Plate Machine.*—In this there is nothing essentially different from the cylinder machine. A glance at the figure will explain all. There are generally two rubbers; and in this form of machine they cannot well be insulated, if required; so the machine cannot be used as a source of both + and − electricity. Instead of glass, ebonite plates may be used, the rubbers being of amalgamated silk.

"III. *Winter's Plate Machine.*—In this the rubber and the points of the prime conductor are more widely separated; and the prime conductor can therefore acquire a higher level (or potential) of charge without discharge over the glass to the rubber. The rubber can be insulated or not, as required. A curious feature is an addition to the prime conductor in the shape of a large ring of brass inclosed in baked wood. This ring increases the 'capacity' of the prime conductor."

The description of Winter's machine is not even supplemented with a figure; and we doubt if any student reading the description will form the faintest conception of the nature of the machine or of the "ring of brass inclosed in baked wood." "Amalgamated silk," too, is a shortened expression, which is, to say the least, as inappropriate as it is uncommon. These descriptions have not been specially chosen for inadequacy. There are numbers no more complete than these.

Probably the chapter which will be found most satisfactor by learners is the long and important Chapter X., which deals with electro-static potential. This, with the exception of the first two or three sections, is very complete and well given. The subject is explained with great clearness, and with abundant reference to numerical calculation.

The chapters on dynamo-electric machines and on motors may also be considered fairly good for an elementary text-book. The learner will obtain in these chapters a sufficient account of the principles of these machines, given with satisfactory clearness.

In his treatment of the subject of units, and particularly of the electro-magnetic units, the author is singularly unhappy. In an elementary book, or in any book on this subject, whether elementary or advanced, it must be considered a fundamental mistake to omit a full and clear explanation of the foundation and derivation of the absolute electro-magnetic unit of resistance; and it is utterly unsatisfactory to give, as a definition of the unit of resistance, the remark merely that "Ohm's law defines the unit of resistance as that through which unit electromotive force gives unit current." It was not in this way that the absolute unit of resistance was fixed upon, and the original definition is certainly worthy of the attention of the student. Taking the statement given above, however, and turning to "Ohm's law" for information, the learner finds no statement of this law in words, but merely the following:—

"Ohm's law is that—

$$C \text{ is proportional to } \frac{E}{R},$$

or

$$C = k\frac{E}{R}."$$

Such a statement as this might perhaps, if reproduced for the benefit of an examiner, serve to conceal the ignorance of the individual under examination, and might leave the examiner so uncertain that he would be obliged, though unwillingly, to award half marks to the answer; but to the student it can do no real good.

There is but one other remark on the electro-magnetic unit of resistance, and it is almost equally infelicitous with what is quoted above. It is contained in a "note" on "Determination of Units," and is to the effect that "resistance can be measured by observation of the heat evolved when a known current flows through the conductor in question." A very slight acquaintance with possibilities in experimenting would dispel any such idea.

In connection with explanations regarding units we meet here the customary sections on "Dimensions of

Units," but it seems to us that too much importance is commonly given to the well-known table of dimensions. Without very full and very clear explanations of the whole subject (and these are not to be found in the book before us), the table and the remarks given in connection with it are worse than useless; they only serve to confuse an intelligent pupil whose own common-sense will carry him safely through any calculation which he can be reasonably expected to make.

We cannot avoid calling attention, before closing this notice, to some most painful defects in style, because it is, we are of opinion, of the utmost importance that students should be trained from the very beginning to write and speak with due respect to ordinary proprieties of literary composition. It is not to the faults of English grammar and to uncouthness of language that we would call attention most particularly, though such faults abound. Thus, on p. 16 the student is recommended to "puzzle this out"; and on p. 72 we find the following sentence:—

"There *will be* a fall of potential, or an electrical hill, from this body A down to the walls, &c. (*sic*). Such *was* the case if only we change the sign of the charge in Chapter IV. § 14."

On p. 248 we find the following:—

"*Failure of a Smee's Cell to decompose Water.*—If the back E.M.F. *e* of an electrolytic cell *would be* greater than the *E.M.F.* E of the battery, then such a battery *will* fail to drive a current through, and decompose, such a cell."

The worst fault in style is, however, the introduction, on every page of the book, often in every line, of contractions of all sorts. Thus we have, through the whole of the electro-static part, + and − for "positive" and "negative"; and we have bodies "+ly electrified" and "−ly electrified." Throughout the electro-chemical part we scarcely once have hydrogen, or zinc, or sulphuric acid mentioned by name, but always H, Zn, and H_2SO_4. This becomes confusing, to say the least, when the author is dealing with the "*Connection between E.M.F.'s and 'Heats of Combination.'*" Here, "if we represent by by H_{Zn} the heat in calories evolved by the solution of 1 gramme of Zn in dilute H_2SO_4, then H_{Zn} is called the heat of combination of zinc with dilute H_2SO_4."

Worse, perhaps, is the use of "ΔV" and "the algebraic sum of the different ΔV's" where "ΔV" stands for the words "difference of potentials." This is done everywhere throughout the first part of the book; and by and by, when we are introduced to ΔV's producing E.M.F.'s, and to "Thomson and Peltier E.M.F.'s," human patience absolutely fails. In the list of abbreviations we are told that a second of time is denoted by 1″ "sometimes." It ought to be *never*.

It is scarcely necessary to say that, were there no merits in the book before us, it would hardly be worth while to enter into a discussion of its faults. But the work is really of great value, and were the materials somewhat rearranged, the writing improved, nine-tenths of the paragraph breaks taken away, and the multitude of notes incorporated with the text, it would prove a most important text-book in electricity and magnetism.

INDO-CHINA AND THE INDIAN ARCHIPELAGO.

Miscellaneous Papers relating to Indo-China and the Indian Archipelago. Reprinted for the Straits Branch of the Royal Asiatic Society. Second Series. Two Volumes. (London: Trübner and Co., 1887.)

THE new series of papers relating to Indo-China, like its predecessor, consists of reprints from various periodicals which are not within the reach of ordinary readers. Thus in the present volumes we find papers of great interest, and some of considerable importance, reproduced from the Journal of the Royal Geographical Society of forty years ago, from the Journals of the Asiatic Society of Bengal, of the Royal Asiatic Society, and from the publications of various Dutch Societies. With regard to the latter, it may be said that they are the most valuable papers in the volumes, for the Dutch have long studied with great assiduity the land and people under their rule in the Malay Archipelago. Their scientific services, in Java especially, are recruited from Holland with the utmost care; the members are spread over the scattered Dutch possessions from Northern Sumatra to New Guinea; they are constantly studying the problems presented to them by man and Nature around them; and the consequence is that the *Verhandelingen* of the Society of Arts and Sciences at Batavia, the *Indische Tijdschrift*, and other publications in the mother country, as well as in Java, are full of papers written by skilled and qualified persons who have devoted special attention to subjects connected with the Malay Archipelago. The editor of these volumes is indebted to these Dutch publications for such papers as that on the rocks of Pulo Ubin, by Mr. J. R. Logan, the greatest English student of this region that ever lived, although there are certain members of the Straits Civil Service who promise to rival him; for Mr. Groeneveldt's "Notes on the Malay Archipelago and Malacca," a modest title under which is concealed a learned examination of a vast quantity of Chinese literature with a view to ascertaining what the Chinese knew about the region; Father Borie's account of the Mantra tribe, and several others.

The experiment of collecting in this way from various sources the papers relating to a particular region is, we believe, a novel one. In this instance it appears to be a success. Here in four volumes, obtainable at a moderate price, we have the contents—so far as they relate to the Malay Peninsula and Archipelago, and appear to a skilled editor to be of permanent value—of more than a score of periodicals, many of which are quite inaccessible to ordinary students, and which, even in London, could only be examined in the British Museum, the India Office, and possibly the Royal Asiatic and Royal Geographical Societies. The Council of the Straits Society, which advanced the funds for this excellent undertaking, is to be congratulated on its public spirit, and we trust it will not lose, even in a pecuniary sense. Whether it does or not, it has placed every student of the region within which its members labour under an obligation by the production of these volumes. Other learned Societies in various parts of the globe might well emulate this example, for there is nothing more laborious or bewildering than to hunt through old periodicals without adequate indexes

and without an exact reference, for a valuable paper. The number of papers of permanent value in these old periodicals is very small: subsequent researches have thrown them out of date; the mere efflux of time has proved some of them to be useless; many deal with temporary subjects, which are now of no importance to anyone. Such a periodical, for example, as the old *China Repository*, printed partly in Canton—the Canton of the old days—now fetches an absurd price. Sets have been sold in recent years at from £30 to £50; yet all that it contains of value now could be placed in two volumes such as these before us. The demand for special works of this character, however, is too small to induce any publisher to incur the risk of producing them; and hence it is that we are thrown back on the learned Societies, which represent the students of to-day, to place within our reach the labours of past generations of scholars, and of the literary and intellectual fathers that begat them. This, however, is a question for the Societies themselves, for their own members must feel more acutely than anyone else the truth of these observations.

We have already mentioned a few of the papers of scientific interest in the present series. If Mr. Logan's paper on the peculiar rocks of Pulo Ubin, an island near Singapore, is not out of date at present, it probably soon will be if the long-promised survey of the part of the Malay Peninsula under British influence is to be thoroughly carried out. Dr. F. Stoliczka has a short paper on some species of Malayan Amphibia and Reptilia, and a longer one on the land-shells of Penang; while Father Borie describes the Mantras, amongst whom he laboured as a missionary for some years. This is one of the aboriginal tribes of the peninsula, which were driven inland by the great Malay invasion of the twelfth century. Of these, the Karens inhabit the north and part of Burmah, the Semangs the States of Kedah, Perak, and Selangore, the Mantras the region lying between the latter territory and Mount Ophir, the Jakons and Sambinbangs the southern part of the peninsula. The writer describes the manners and habits of the people in some detail. A most interesting paper, and one of the longest, is Dr. Friederich's account of the language, literature, religion, and castes of the people of Bali, an island which occupies a peculiar relation in the history of the civilization of the Malay Peninsula and Archipelago. The editor in his introduction describes that position in these words:—

"The continued existence, in unabated vitality, of a nationalized Hinduism, blended with pre-Hindu customs and practices, among a spirited and vigorous people is not only . . . a kind of commentary on the ancient condition of the natives of Java, it allows us also to draw a fair inference as to the kind of Hinduism at one time prevailing in other parts of Malaysia less favoured by historical records, where ruthless Islam has since obliterated to a great extent the traces of other creeds, traditions, and institutions. It is, indeed, essential to a proper understanding and estimate of the religious and social condition of the various and wide-spread Malayan tribes that the influence which Hindu civilization has, in a greater or lesser degree, exerted upon them, should as far as possible be investigated."

It should be mentioned that the last number of the Proceedings of the Dutch Geographical Society contains a paper on the same subject by Count Limburg Sturm, who visited the island last year.

Finally, there are certain "Notices on Zoological Subjects," and "Descriptions of Malayan Plants," reprinted from an English periodical published at Bencoolen nearly seventy years ago, with a note to the letter by Sir Joseph Hooker and Mr. Hervey, correcting the terminology. In the preface the editor quotes part of a letter from Sir Joseph pointing to a speedy investigation of the flora of the Malay Peninsula, for which he has urged the Colonial Government to contribute funds. Seeing that Dr. Rost has had to go back to 1820 for an account of the flora, it seems almost time that Sir Joseph Hooker's advice should be taken by Sir Cecil Smith and the Legislative Council of the Straits Settlements.

THE ZOOLOGICAL RESULTS OF THE "CHALLENGER" EXPEDITION.

Report on the Scientific Results of the Voyage of H.M.S. "Challenger" during the Years 1873–76, *under the command of Capt. George S. Nares, R.N., F.R.S., and the late Capt. F. T. Thomson, R.N.* Prepared under the superintendence of the late Sir C. Wyville Thomson, Knt., F.R.S., &c., and now of John Murray, one of the Naturalists of the Expedition. Zoology—Vol. XXII. (Published by Order of Her Majesty's Government, 1887.)

VOLUME XXII. contains the Report, by Dr. Günther, Keeper of the Department of Zoology in the British Museum, on the deep-sea fishes collected during the cruise.

Originally it was intended to fix an arbitrary depth as distinguishing between the shore and deep-sea fishes, and accordingly, in the author's previous Report on the shore fishes of the *Challenger* Expedition, all those fishes captured at a less depth than 350 fathoms were treated as more or less littoral forms. However, the subsequent Norwegian and North American explorations brought to light instances of fishes with an unmistakably bathybial organization occurring at a much shallower depth than the forms discovered by the *Challenger*; or, on the other hand, showed that certain littoral forms descend not only to 100 but even to beyond 300 fathoms.

In the present Report, the 100-fathom line is adopted as the boundary at which, with the extinction of sunlight, the bathybial fauna commences, sporadically, no doubt, and largely mixed with surface forms.

The material which forms the subject of this Report consisted of 794 specimens, of which 610 were obtained during the voyage of the *Challenger*, 88 on the cruises of the *Knight-Errant* and *Triton*, and 96 from other sources. These specimens are referred to 266 species, 177 falling to the share of the *Challenger*, and 14 being due to the exploration of the Faroe Channel. The number of new species discovered by the *Challenger* amounts to 144, whilst by the deep-sea exploration of the Faroe Channel 10 species have been added to the fauna of the British seas.

In the introduction we have a history of our present knowledge of the fish-fauna of the deep-sea, some account of the characteristics of deep-sea fish, and an account of their vertical and horizontal distribution.

While no distinct bathymetrical zones, characterized by peculiar forms, can be defined, yet the following table clearly shows that the abundance of fish life decreases with the depth. There have been found between

Fathoms.	Species.
100–300	232
300–500	142
500–700	76
700–1500	56
1500–2000	24
2000–2900	23

While no doubt this decrease in numbers is partly due to the extreme difficulty of investigating the deep-sea fauna, it cannot but be also regarded as pretty certain that, while locally abundant as to individuals, the number of species found is but small.

The descriptions of the new genera and species, though abounding with interesting details in reference to the many strange forms described, cannot with the space at our disposal be even summarized,—they are such as would have been expected from the known skill and judgment of Dr. Günther; but we must find room for some allusion to the Report on the structure of the phosphorescent organs, on the head of Ipnops, by Prof. H. N. Moseley, and on the structure of the phosphorescent organs of fishes, by Dr. R. von Lendenfeld.

In *Ipnops murrayi* the eyes as well as the optic nerves are completely absent, but a pair of symmetrical luminous organs are to be found on either side of the median line of the upper flattened surface of its head, the upper wall of the skull where it covers them being completely transparent.

These phosphorescent organs are composed of hexagonal columnar masses, arranged with considerable regularity in rows, and resting inferiorly on a pigmented connective-tissue layer. Each hexagonal column is composed of a number (from thirty to forty) of transparent rods, disposed side by side at right angles to the outer surface of the organ, and with their bases applied against the concave surface of large hexagonal pigment cells, one of which forms the base of each hexagonal column. The basal pigment cells are also hexagonal in outline, and are cup-like, concavo-convex in form, and of the same breadth as the hexagonal columns. These organs receive a rich blood supply, and there appears little room for doubt but that the nerve supply comes from the fifth nerve. No trace of any other nerve supply has been found. From a comparison of these organs with those of a similar nature in other fish, the author concludes that they are but highly specialized and enormously enlarged representatives of the phosphorescent organs on the heads of such allied Scopelids as *Scopelus rafinesquii* and *S. metopoclampus*.

The Report of Dr. von Lendenfeld is of a more general character, treating as it does of the phosphorescent organs of most of the known phosphorescent fishes, though not alluding to those of Ipnops. These organs are classified into the regular ocellar organs and the irregular glandular organs. Both these classes are again subdivided in reference to their form or position; and in conclusion we have a comparison of the different phosphorescent organs of fishes, and of these as compared with similar organs in other animals.

Dr. von Lendenfeld sums up his investigations as follows:—(1) The phosphorescent organs of fishes are more or less modified glands which have partly been developed from simple slime-glands in the skin, and partly in connection with the slime-canal system; (2) the typical clavate cells are modified gland-cells; (3) the accessory reflectors and sphincters are developed from the skin around and below the gland; (4) the large suborbital organs are innervated by a modified branch of the trigeminus, and the other organs by the ordinary superficial nerves.

A splendid atlas of plates accompanies this volume. Of these, sixty-six represent the new species described by Dr. Günther, and several of them are folding plates; two illustrate the anatomy of the phosphorescent organs of *Ipnops murrayi*; and the remaining five are drawn by Dr. von Lendenfeld and illustrate in a very beautiful manner his Report on the phosphorescent organs just alluded to.

SALINE DEPOSITS.

Die Bildung des Natronsaltpeters aus Mutterlangensalzen. By Dr. Carl Ochsenius. (Stuttgart: E. Koch, 1887.)

THIS book is a very valuable contribution to the history of saline deposits in general, but it is especially useful on account of the author's detailed description of the salt-beds of Chili and Peru, to the study of which he mainly devotes his attention. He discusses the various theories which have from time to time been advanced to account for the formation of Chili saltpetre (sodium nitrate), and shows that it must be regarded as the product of the action of oxidizing guano on certain mother-liquors containing carbonate of soda.

The salt-beds on the west coast of South America are found in the rainless district which stretches from Payta (near Amotape), in Peru, as far south as the twenty-sixth parallel. This region forms a narrow strip along the coast-line, and rarely exceeds twenty-five miles in width. It is bounded on the east by a chain of the Andes, and in the southern portion of the district the coast is fringed with low-lying hills, known as the coast Cordilleras. The author considers that, before the upheaval of the Andes, salt began to deposit in certain bays, which had been wholly or partially shut off from the sea by the gradual formation of an intercepting bar. Then, while the process of evaporation was still incomplete, the district was raised by volcanic action, and the mother-liquors from the salt lakes eventually escaped, running down into the valleys, and, where they encountered no obstacle, reaching the sea. The coast Cordilleras acted as a barrier in the southern portion of the district; while in the northern part the liquors doubtless returned to the sea. The volcanoes which produced the aforesaid upheaval exhaled immense volumes of carbonic acid gas, and the author considers that a portion of the sodium chloride in the mother-liquors was thus converted into sodium carbonate. (The co-existence of borates goes far to confirm the source of carbonic acid.) The coast in this part of Chili is studded with small islands containing deposits of guano

rich in ammonia. The guano dust is carried by the prevailing west winds far into the country, and would fall into the mother-liquor lakes, where, on exposure to the air at a warm temperature, it would gradually oxidize to nitrate, and, acting on the sodium carbonate, would form sodium nitrate (Chili saltpetre).

The "caliche" (crude saltpetre) is most variable in appearance and in the percentage of nitrate which it contains. The various substances, other than sodium nitrate, which are found in the Tarapaca and Atacama deposits are described at length by the author, who compares them with those which are found at Stassfurt, and he traces in the comparative prominence of the more soluble salts in the Chilian deposits a further confirmation of his theory that the nitre-beds are formed from mother-liquor salts.

The book is well indexed, and is supplied with a map and several sections of the district described.

J. I. W.

OUR BOOK SHELF.

Tenerife, and its Six Satellites. By Olivia M. Stone. In Two Vols. (London: Marcus Ward, 1887.)

A GOOD book on the Canary Islands, which have been of so much service to many an invalid, has long been wanted; for, as Mrs. Stone says, many parts even of the best-known islands of Tenerife and Gran Canaria are untrodden ground to English people, and are but little known to persons of any other nationality. Mrs. Stone supplies all the information that can be needed by the most exacting visitor to the islands, or by persons who may wish to read about them at home. As she has already shown in her "Norway in June," she has excellent powers of observation, and knows how to give a clear and effective account of all that she sees in her travels. In the present work her descriptions are all the more vivid because they were written "on the spot," when everything she wished to set down in her narrative was still fresh in her mind. To the Island of Hierro, to which she and her husband seem to have been the first English visitors, she devotes a good deal of attention; and what she has to say about that "solitary, happy, singular" island is full of interest, and would alone have justified her, if justification had been necessary, in making her travels in the Canary Islands the subject of a book. In an appendix she presents a useful epitome of all necessary expenses connected with her tour.

Through Central Asia. By Henry Lansdell, D.D. (London: Sampson Low, 1887.)

THIS is a popular edition of the author's well-known "Russian Central Asia, including Kuldja, Bokhara, Khiva, and Merv." He has omitted many whole chapters and most of the notes, thinking it best that the present edition should consist chiefly of a personal narrative. Any student who may desire fuller information regarding Central Asia is referred to the original work, in which Dr. Lansdell gives 4300 species of fauna and flora in about twenty lists with introductions, adds a bibliography of 700 titles, and treats more or less fully of the geography, economy and administration, ethnology, antiquities, history, meteorology, geology, zoology, and botany of all parts of Russian Turkistan, Kuldja, Bokhara, Khiva, and Turkmenia, down to the frontier of Afghanistan. To the new and abridged edition he has added an appendix on he delimitation of the Russo-Afghan frontier.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

The Star of Bethlehem.

REFERRING to the hypothesis in your last week's issue, that the star of Bethlehem was Venus, I would point out that 1180 synodical periods of Venus (*i.e.* 1180 × 583·92 = 689,025 mean solar days) take us back from October 28, 1887—when Venus was at her maximum brilliancy as a morning star—to only May 3 of the year 1 A.D. instead of December 25 of the year 1 B.C. For the number of days from October 28, 1887, to December 25, 1 B.C., is 689,155 (viz. 1887 × 365·2425 = 689,213 − 64 + 6 = 689,155). This would appear to show, either that the birth of Christ took place about May 3, or that Venus at her maximum brilliancy as a morning star was not the star of Bethlehem. I should be glad of your remarks on this.

JOHN T. NICOLSON.

20 Thirlestane Road, Edinburgh, December 26, 1887.

I INFER from the article entitled "The Star of Bethlehem" (NATURE, December 22, 1887, p. 169) that the writer supposes the craze he deals with did not exist until Venus became a morning star. It was equally prevalent here when, early in the year, she was an evening star, as the following fact will show. On May 21, 1887, a lady wrote me as follows:—"Will you kindly tell me what people mean about '*a wonderful star*'? All our servants are talking about it. . . . Some call it '*the star of Bethlehem.*' . . . I hear it is '*wonderfully bright!*'"

Torquay, December 26, 1887. WM. PENGELLY.

IN regard to the so-called "star of Bethlehem," Prof. C. A. Grimmer, in "Life from the Dead," No. 69 (August 1879), p. 267, wrote:—"It will be seen in 'Cassiopeia's Chair,' and will be accompanied by a total eclipse of the sun and moon. The marvellous brilliancy of the 'star of Bethlehem' in 1887 will surpass any of its previous visitations. It will be seen even at noonday, shining with a quick flashing light the entire year, after which it will gradually decrease in brightness, and finally disappear." E. COATHAM.

January 2.

On some Apparent Contradictions at the Foundations of Knowledge.

IN Chapter III. of Mr. Herbert Spencer's "First Principles" (p. 47, under heading, "Ultimate Scientific Ideas"), are treated the subjects of space and time. Here contradictions and difficulties of an apparently insuperable character are encountered in the attempt to define the nature of space and time, and the existence of these difficulties is frankly acknowledged. But with all the respect that is here due, it appears difficult to admit that these apparent contradictions are necessary, and in regard to space, in the first place, it will be my object here to suggest a remedy.

I will first quote some passages from the "First Principles" (5th edition) relating to this question, viz. as follows:—

"Thus as space and time cannot either be nonentities, nor the attributes of entities, we have no choice but to consider them as entities. But while on the hypothesis of their objectivity, space and time must be classed as things, we find on experiment that to represent them in thought as things is impossible" (p. 47).

It will be observed here that we encounter the apparent contradiction that those are classed as things which it is found impossible to represent in thought as things.[1]

[1] Experiment would then indirectly say that space and time were *not* things.

Then it is remarked, "To be conceived at all, a thing must be conceived as having attributes" (p. 47); and yet the author admits that it is impossible to assign any attribute to space (p. 48). So that it would appear from the last impossibility that space is *not* a thing (or entity).

It is added, "All entities, which we actually know as such, are limited" (p. 48). But, on the other hand, it is allowed that, "Of space and time we cannot assert either limitation or the absence of limitation" (p. 48).

It is observed also as follows:—"Nor are space and time unthinkable as entities, only from the absence of attributes" (p. 48). This would involve the conclusion apparently that that is considered to be an entity which is absolutely "*unthinkable*" as such.

Must there not be some flaw here, and some solution possible?

I have to propose—and this may appear very bold at first sight—that space is a non-entity. I must explain my meaning more fully. The first question or difficulty will be, How can we conceive of space (a void) or even talk of it, if it be a non-entity or nothing? In fact, on p. 177 is the remark, "Nothing cannot become an object of consciousness."

In reply to this, I would venture to suggest that under certain conditions, nothing can become an object of consciousness, viz. *by contrast with something*. We can be conscious of an absence. Darkness can become an object of consciousness by contrast with light. So space in itself—which I contend is nothing—is an object of consciousness [1] by contrast with matter.

We consider space to be an entity, I fancy, because of our experience with palpable air, &c., which (for convenience, but inaccurately) is called space. Space *per se*, an absolute void, we have no experience of. We measure all so-called spaces with matter—standards made of matter. We estimate how much solid matter is absent in a room (for instance), which we call its "volume." Mathematical lines are unconsciously figured as material no doubt from our habit of drawing them; and the spaces of triangles, &c., are usually filled out with solid matter.

It would be ridiculous (as it seems) to ask what would happen if a void disappeared. It cannot disappear because it is *already* nothing.

In regard to matter, we can conceive a certain volume of it, a certain volume added to that, &c.; and no doubt we cannot easily limit the conceivability thus extending to a larger volume. But we are not forced (by necessity as it were) to conceive an infinite volume of any entity or actually existing thing; and it appears that a void is excluded from the category of the unknowable, as we cannot expect to know anything about nothing.

Why do we hear of the creation of matter speculated about (as an inadequate attempt at explanation), but the creation of space regarded as absurd? [2] Because the first is an entity and the second is not. A non-entity cannot be supposed to be created, or it is absurd to ask the question.

One may encounter difficulties of explanation *by assuming too much to exist*—too much to explain, it appears. So I account for some of the startling contradictions supposed to exist at the basis of knowledge. What is nothing, if a void be not nothing? In order to be face to face with nothing and contrast it with something, we should not have to abolish a void, I venture to think.

Another matter seems important. On p. 34 ("First Principles") is the following, viz.:—"Did there exist nothing but an immeasurable void, explanation would be needed as much as now. There would still arise the question, How came it so? If the theory of creation by external agency be an adequate one, it would supply an answer; and its answer would be—Space was made in the same way that matter was made. But the impossibility of conceiving this is so manifest, that no one dares to assert it. For if space was created it must have been previously non-existent. The non-existence of space cannot, however, by any mental effort be imagined. . . . We are unable to conceive its absence either in the past or in the future."

[1] It appears that in order to assert an existence there must be a conception of non-existence as a contrast; otherwise the word "existence" would seem to have no distinct meaning. If matter be an existence, its absence (or a void) must be a non-existence. In other words, an absolute void (vacuity) is contemplated as the absence of existence.

[2] The author remarks of space, on p. 48, as follows:—"The only attribute which it is possible for a moment to think of as belonging to it, is that of extension; and to credit it with this implies a confusion of thought. For extension and space are convertible terms."

In regard to the commencing passage, viz. "Did there exist nothing but an immeasurable void, explanation would be needed as much as now," it might be asked, When would you be satisfied with an explanation? Explanations must finish somewhere; they finish at existences, I should fancy, and cannot extend to their absence. It is this demanding explanation perpetually, without conceived limit, that leads to the contradictions and attempts at defining nothings—as seems manifest. Extraordinary as this view taken by the author appears, it is consistent with his assumption that an absolute void is an existence or thing, whereby it is put on the same footing as matter. But observe to what this further leads.

First, the inconceivable existence of an infinite thing without attributes is assumed. Second, its non-existence cannot "by any mental effort be imagined." This means, in my view, that all attempts to imagine it *more* nothing than it is, are futile. What better definition of nothing could we have than that we cannot assert it to have "either limitation or the absence of limitation," or it is "unthinkable" as an entity "from the absence of attributes"?

Well, in this way, actual existence of something which is put on the same footing as matter seems to be made a necessity for an infinite past time; as (unlike matter in this respect) we cannot even *imagine* change here—in fact, the original creation of this thing (a void) no one dares to assert." In the same way, no one would venture to assert the creation of a mathematical line, or a mathematical plane, *i.e.* the creation of extension [1] of one, two, or three dimensions.

From the author's conclusion that space is an entity, it may be reasoned, then, that, since we must apparently have one existence for an infinite past time, we may as well have two, or include matter. Hence, with all the deference which the views as a whole in the "First Principles" demand, I would point out that in this way support is given to the idea of existence for an infinite past time (impossible to grasp fairly, as the author concedes)—which, as I contend, is not warranted by the facts.

S. TOLVER PRESTON.

30 Rue de la Clef, Paris, December 1887.

[1] The author remarks that "Extension and space are convertible terms" (p. 48). I may express my agreement with the author as to the inadequacy of the theory of the "creation" of matter, as an explanation.

Christmas Island.

HAVING read with much interest the description of Christmas Island by Captain Aldrich and Mr. Lister, I have endeavoured to interpret some of the facts there given in the light of my own examination of similar islands in the Western Pacific. As pointed out by Captain Wharton, the complete casing of an island, 1200 feet in height, with coral rock is somewhat unusual. This may find its explanation in in the absence of stream-courses and ravines, a circumstance from which I infer that the island has not been exposed sufficiently long, since its upheaval, to the denuding agencies. When its surface has been extensively carved out by the action of running water, the old volcanic peak, which these upraised reefs envelop, will in all probability be exposed. Christmas Island, therefore, has still the early part of its story to unfold.

The three tiers of cliffs evidently mark pauses in the elevation. As they appear to decrease in height with the ascent, it would seem that older lines of cliffs on the upper slopes of the island have been removed to a great extent by denudation. The principal features of the movement of upheaval appear to resemble those of which similar upraised coral islands give evidence in the West Indies, Western Pacific, and other regions of elevated coral reefs. Protracted elevatory movements of from 100 to 300 feet are separated by long pauses, during which cliffs are worn back by the waves, and the reefs grow seaward: hence the terraced profiles of these islands. I have pointed out that in the Solomon Group these protracted movements consist of a succession of small upheavals of usually 5 or 6 feet at a time.

17 Woodlane, Falmouth. H. B. GUPPY.

A Mechanical Cause of the Lamination of Sandstone not hitherto noticed.

THE lamination of sedimentary rocks is usually attributed to the successive deposition of sediment of varying degrees of fineness or coarseness. Currents of water have a selective action

on the materials that are swept along by them, by which grains of one size and weight are laid down at one time, and of another size and weight at another. Changes in the nature of the material in suspension also occur through which the deposit may be at different times more siliceous, argillaceous, or calcareous. This is doubtless in most cases a true explanation of the cause of lamination in rocks, but it is not a full one, nor does it account for stratification such as I am about to describe.

In sand dunes composed entirely of siliceous grains such as are seen on the west coast of Lancashire between Liverpool and Southport, a strong false-bedded lamination is often beautifully developed. This is best seen when the sand-hills are moist from recent rainfall, and the talus has been cut away by a high tide, leaving a vertical face of sand to the shore side. After this has occurred a gentle wind will weather out the structure of the sand-hill in a remarkable manner. The layers often stand out several inches in projecting mouldings and fillets, while the finer laminæ are wonderfully developed. I have often minutely

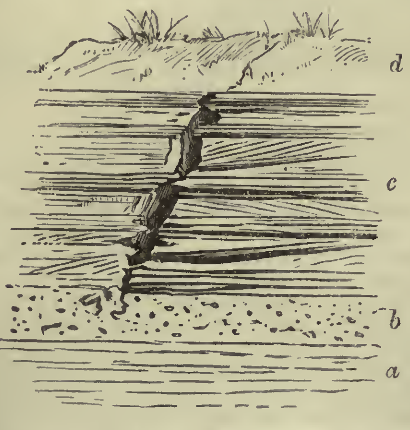

Fig. 1.—View of sand-dune, showing the bedding and laminæ weathered out by denudation. *a*, shore; *b*, loose talus; *c*, vertical cliff of sand; *d*, surface of sand-dune.

examined the constitution of these beds, but have been unable to detect any difference in the sizes of the constituent grains of the several beds or laminæ. What makes the fact more striking is that the grains are generally and in many cases much rounded. An examination, however, shows that the laminæ projecting from the face of the sand-cliff are much harder and more solid than the portions between them that have weathered back. They can, in fact, be broken off in pieces by the fingers without crumbling. The grains of sand, I must observe, are only temporarily bound together by the capillary attraction of the water.

The explanation which suggests itself to me is that the grains of sand, according to the state of the weather during deposition, are at one time more completely aggregated than at another. The shore sand, I have noticed, is greatly affected by the state of the water it is laid down by. In one place may often be seen a stretch of hard fine sand, while in another at the same level the sand may be soft, both being at the same point of saturation. It is well known to builders that pouring water on loose sand tends to solidify it, therefore it is most probable that the state of the weather influences the solidity of aggregation of the surface of the sand dunes and assists to build up layers of different density.

Between the projecting fillets already described as weathered out of the sand cliffs the sand is looser and more porous, and, drying faster, falls away from the face at a greater rate than the compacted beds. In sand heaped together by the wind there are few, I should think, would *a priori* look for much internal structure; yet here are the most undoubted evidences to the contrary which are generally passed by, being looked upon as a matter of course not demanding further thought! If we consider in what way the constituent grains naturally arrange themselves by gravity, we shall, I think, get an additional clue to the cause of lamination. Even if the grains were as round as shot they would by gravitation tend to arrange themselves in parallel planes, the upper grains falling into the interstices of those next below them, so—

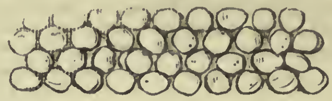

Fig. 2.

If, on the contrary, the grains have a long and short axis, they will tend to lie with the longer axis parallel to the plane of deposition, so—

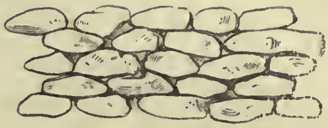

Fig. 3.

With irregular fragments the arrangement will not be so perfect, but they also will tend to be laid down in definite planes.

An examination of specimens of laminated sandstone shows that a fracture vertical to the plane of lamination exhibits a more jagged surface than a fracture parallel to the plane of lamination. This it is that gives the strength to sandstone to resist transverse stress.

It is thus seen that nature adopts the same principle to build up sandstone that a mason does to build a wall. From the way in which the particles arrange themselves a natural "bond" is produced. The grains "break joint," as it is technically called—that is, the joints are not vertically over each other—while the planes of deposition correspond to the "courses" of a wall. The principle here explained I have seen well exhibited in conglomerates formed of flattish oval pebbles. The mode of aggregation of the particles of a sedimentary rock, due to the ordinary dynamical laws governing deposition, and independent of the coarseness or fineness of the grains of successive layers, is an important factor in its constitution, which seems hitherto not to have attracted much attention. T. Mellard Reade.

Total Solar Eclipse of October 29, 878.

In Nature for March 11, 1875, vol. xi. p. 365, a computation is given of this eclipse, based on an entry in the "Annales Fuldenses," which runs thus: "Sol quoque in 4 kal. Novembris post horam nonam ita obscuratus est per dimidiam horam, ut stellæ in cœlo apparent, et omnes noctem sibi imminere putarent."

The computer found that the sun rose on that day at Fulda at 7h. 12m. apparent time, 6h. 57m. mean time, that the partial phase began at 0h. 56m., and ended at 3h. 24m., totality commencing at Fulda at 2h. 9m. 32s. local mean time, and continuing 1m. 41s. till 2h. 11m. 13s. He seems to have been puzzled, however, by the statement of the annalist that the darkness occurred "post horam nonam," observing plausibly enough that the ninth hour from sunrise would be 4 p.m.

It is shown, however, in Dr. Smith's "Dictionary of Christian Antiquities," vol. i. p. 793, that the day then employed by the Church was the natural day extending from sunrise to sunset, which was conceived to be divided into twelve hours (shorter of course in winter than in summer); so that the first hour was the twelfth part of the natural day, which began with sunrise; the sixth hour that which ended when the sun crossed the meridian, and so on.

The question, then, which arises is this: At what point of local mean time did the ninth natural hour end at Fulda on October 29, 878?

The sun rose at 7h. 12m. apparent time: this would give a semi-diurnal arc of 4h. 48m., or 9h. 36m., as the duration of the natural day, one-twelfth part of which, or 48 minutes, would be the length of the natural hour. As nine such hours would contain 432 minutes, it is clear that the ninth hour after 6h. 57m. the local mean time of sunrise would end at 2h. 9m., and the half-hour of darkness mentioned would have extended from 2h. 9m. to 2h. 33m. As the computer reckoned that totality lasted from 2h. 9m. 32s. to 2h. 11m. 13s., the obscuration would have been gradually passing away during that period.

The coincidence between the record and the calculation is a very striking one, and testifies at the same time to the veracity

of the Benedictine monks of Fulda, the trustworthiness of the lunar and solar tables, and the accuracy of the computer who brought out so marvellously correct a result without knowing that it agreed exactly with the true meaning of the record.

No doubt equal credit may be given to the computer's statement that this eclipse was total in London, totality continuing at St. Paul's from 1h. 16m. 20s. to 1h. 18m. 10s. local mean time.

C. S. TAYLOR.

Height of T'ai Shan.

A FORMER student of mine, Mr. S. Couling, has recently ascended T'ai Shan, the loftiest of the sacred mountains of China, and one of the most ancient and popular places of pilgrimage. He believes that the height of it above the surrounding plain has never before been measured, and has sent me his observations to reduce. The elevation from the plain to the summit comes out at 4780 feet; whilst a temple vaguely stated to be about 400 feet below the summit is, as ascertained by barometer, 4485 feet above the plain.

SILVANUS P. THOMPSON.

The Shadow of a Mist.

LIVING on the Blue Mountains at an elevation of 5000 feet, I am frequently astonished at the ever varying beauty of the mists and clouds. But a short time ago it was my good fortune to see the shadow of a mist, itself not visible.

On the evening of November 16, shortly after 7 o'clock in the evening, I was watching the electric light with which the military authorities were experimenting at Port Royal, 15 miles distant in a straight line. The light at times was so brilliant that the shadow of a person standing 20 feet from the house was distinct on the white-painted front, even when he held a lamp partially turned down close to his body on the side next the house. Rain was falling, but so slightly that there was no need for an umbrella. No mist or cloud was visible in the direct line to Port Royal, and yet a net-work of shadow was thrown on the house, the meshes of which were 3 or 4 inches in width. The shadows were all in motion, moving from east to west, in the direction of the scarcely noticeable breeze; individual portions of the meshes disappearing and re-forming as they moved, so that it was quite dazzling to look at the shadow, reminding me of the ripple on water as seen against a strong light. A puff of tobacco smoke had a shadow only when an inch or two from the house, so that the mist must have been much denser, and yet it cannot have been of any great breadth, or the shadow would have been uniform instead of reticulated. No doubt many of your readers can explain this appearance, which to me seemed so singular.

W. FAWCETT,
Director of Public Gardens and Plantations.

Cinchona, Gordon Town P.O., Jamaica, December 1, 1887.

The Ffynnon Beuno and Cae Gwyn Caves.

IT would seem that so long as the controversy with regard to the contents of these caves is confined to Dr. Hicks, Prof. Hughes, and Mr. W. G. Smith, the points at issue will never be decided. Dr. Hicks argues most needlessly for the *pre*-Glacial age of the cave deposits; Prof. Hughes calmly assumes that the outside deposits are *post*-Glacial; and many geologists must be heartily tired of hearing these two gentlemen contradict one another without defining what they mean by the terms Glacial and post-Glacial.

The fact is that the St. Asaph drift (to which Prof. Hughes now admits the outside deposits belong) is part of the later Glacial series of Northern England; and Prof. Hughes has no right to call it post-Glacial without defining what he means by that term. Most people call them Glacial deposits. If therefore the cave-deposits are older than this drift, they are not necessarily *pre*-Glacial, as Dr. Hicks maintains, but only anterior to what Mr. Mellard Reade terms the marine low-level boulder-clays. Now many think that these clays and their associated sands are coæval with, or newer than, the so-called post-Glacial river-gravels of Southern England. It is not surprising therefore that the cave fauna should be the same as that of the river-gravels, and it is perfectly needless to compare it with the fauna of the Cromer Forest bed.

In Lincolnshire the same marine shells occur in sands and gravels beneath the latest sheet of boulder-clay, and a gravel beneath the same clay at Burgh has yielded teeth and bones of *Elephas antiquus*, *Rhinoceros leptorhinus*, and *Bos primigenius*. These beds are on the same line of latitude as St. Asaph, and are probably of the same age as that drift; but it may be that neither of them are older than the oldest river-gravels of the Cam or Thames valleys.

It has been repeatedly pointed out that the terms Glacial and post-Glacial cannot be used as conveying any idea of relative age except along one and the same parallel of latitude, and it is rather surprising that the Woodwardian Professor of Geology should seem to be unaware of this. If by post-Glacial Prof. Hughes means later Glacial or newer Pleistocene, everyone will probably agree with him, but he confuses the issue by his bad choice of terms.

The palæontological evidence is really of no value—the argument leads nowhere; what we want is an expression of opinion by some geologist who has seen the locality and the recent excavations, regarding the explanation proposed by Prof. Hughes, viz. that the present position of the bones beneath the marine drift is due to the falling in of the roof of the cave near one entrance, while the animals may have got into the cave by another opening. Many geologists have visited the locality—will some of them communicate their views on this point?

A. J. JUKES BROWNE.

Southampton, December 28, 1887.

THE OLD MOUTH AND THE NEW: A STUDY IN VERTEBRATE MORPHOLOGY.

"THE question of the nature of the mouth," says Prof. Dohrn in one of the first of his celebrated "Studien zur Urgeschichte," "is the point about which the whole morphological problem of the Vertebrate body revolves." According to Dohrn, the present mouth of Vertebrates arose from the coalescence of a pair of gill-clefts. In this we have an example of Dohrn's principle of change of function, and also, as I hope soon to demonstrate, of Kleinenberg's law of the substitution of organs. I do not now wish or intend to give an account of the researches by which Dohrn showed that the mouth in some cases first arises as a pair of lateral invaginations of epiblast, still less of my own small contribution to this question, which consisted in recording the facts that the mouth also resembles a gill-cleft in some other particulars.

It suffices here to say that these researches have not yet been refuted, and that the view that the present mouth of Vertebrates is, so to speak, a new structure, rests on a very sound foundation.

With the blastopore as the foundation of mouth and anus I have here no concern, nor have I any sort of sympathy with the upholders of a theory which has been condemned and rejected by embryologists such as Lankester, Kleinenberg, and Salensky.

The problem I have to discuss is, granted that the present Vertebrate mouth is a new[1] structure, what traces, if any, are to be found of the old mouth? It is conceivable, and I strongly emphasize the point, that the old mouth might have disappeared, even from the development, without leaving a trace behind.

We seem to be gradually getting out of the idea that ontogeny is even a fair repetition, much less a perfect one, of phylogeny, for absolutely rudimentary organs (organs performing no function at all) are only retained as larval or embryonic organs, as the basis or *Anlage* of other organs, or, finally, because they are inseparably connected with the development of other organs. Of the latter a fair case, it seems to me, is to be seen in the rudiment of the parietal eye in the higher Vertebrates. This organ, functionless except in a few fishes and reptiles, possibly only reappears in the development because it is intimately connected in some way or other with the paired eyes.

A still better example is, I think, to be met with in the

[1] It is rather paradoxical to speak of a thing as new which has existed in its present form for untold millions of years.

rudiments of the gill sense-organs and ganglia described by Prof. Froriep in Mammalia. (Of these I hope to give a fuller account in connection with other work.) I find them in lizards, crocodiles, and birds; and there can be little doubt that they exist as rudiments in all animals above fishes and amphibia. Their recurrence has its explanation in that they probably form the *Anlage* for certain portions of the cranial ganglia.

It was Dohrn who first hinted, in his work on "Der Ursprung der Wirbeltiere," published in 1875, that the hypophysis cerebri represented the last remains of the old mouth, and that it must have opened on the dorsal surface, after passing between the crura cerebri.

This idea he soon gave up, and indeed, in the work above mentioned, he inclined to the view that the opening lay somewhere in the region of the medulla oblongata. Since then he has relinquished, for the time, the search for the old mouth, and has advised others to do the same.

His first hypothesis has more recently been advanced as new by Prof. Owen and Mr. J. T. Cunningham. Both of these writers hold very slightly different views from those originally suggested by Dohrn.

Some of the statements which I am about to make appear on the surface to bear slight resemblance to Cunningham's views, but, as I hope will be seen, nothing could be further from the truth. Cunningham, starting from Balfour's well-known, and now universally accepted, belief that the spinal cord and brain were once an open plate, advocated, as the latest discovery of Vertebrate morphology, the view that the infundibulum, whose walls consist of nervous matter and nothing else, is the vestige of the old mouth which pierced the brain.

One cannot but marvel at the rashness of an hypothesis which annexes, without more ado, a portion of the nervous system, and proclaims it to all the world as the remnant of a former passage from the exterior to the stomach of the animal!

Cunningham overlooks entirely the nature and exceedingly complicated development of the processus infundibuli, or nervous portion of the hypophysis.

Although, thanks to Rabl-Rückhard and others, we have obtained a certain amount of light on the nature of the pineal gland or epiphysis, the body (hypophysis), at the opposite end of the third ventricle still remains one of those organs on which all sorts of speculations may be made, with impunity. Some of the explanations offered are in accordance with certain facts of its development. Others, on the contrary, accord with no known fact of embryology.

The nervous part—or, as I shall call it, the *neural hypophysis*—has been considered by Rabl-Rückhard as a gland secreting cerebro-spinal fluid. I must, however, express a strong opinion that such a glandular function is extremely improbable, for the conversion of a piece of nervous tissue into a gland is absolutely without parallel.

Goette and Wiedersheim both regard the nervous part as a remnant of a sense-organ; against which view *a priori* little or nothing can be said. The mouth part or *oral hypophysis* was finally classed by Dohrn as the rudiment of a pair of gill-clefts—a supposition not wholly unsupported by its developmental history. It has also, not unnaturally, been looked upon as a remnant of a mouth-gland.

Prof. Hubrecht made it the basis of his comparisons of Nemertea and Vertebrata, and saw in it the remains of the Nemertean proboscis, the Vertebrate notochord being the homologue of the proboscis sheath—comparisons which appear to me to be as little capable of support as those of the same investigator between the Vertebrate and Nemertean nervous systems.

And so, after all, on turning to Wiedersheim's latest book, "Der Bau des Menschen," we read: "The hour of the release of the hypophysis cerebri from its obscure position has not yet struck, and the problems it presents are rendered more difficult in that it develops from two different points—from the brain (infundibulum) and from the epiblast of the primitive pharyngeal involution."

For what we know of the facts of its anatomy and development we are mainly indebted to five distinguished morphologists: Profs. W. Müller, Goette, Mihálkovics, Kölliker, and Dohrn. In the following very brief summary I partly follow Kölliker's account (in his valuable "Entwickelungsgeschichte des Menschen," 1879), which, for the time it was written, is by far the most complete we possess.

My own researches on Sharks, Ganoids, Dipnoi, Cyclostomata, Amphibia, Lizards, Snakes, Crocodiles, Birds, and Mammals, mainly confirm Kölliker, who, in his turn, has taken the greater portion of his account from the beautiful classic of Mihálkovics.

The hypophysis cerebri is composed of two parts: the one, *neural hypophysis*, derived from the nervous system; the other, *oral hypophysis*, from the epiblast in the region of the mouth.

The oral hypophysis is formed early in development as an epiblastic involution towards the end of the notochord, *i.e.* towards the hypoblast, and in the direction of the base of the brain. In some cases it may even grow in the direction of a process of hypoblast immediately below the anterior end of the notochord. But, except in Myxine, it never fuses with the hypoblast. It afterwards becomes pinched off from the pharynx, and gets thus to lie on the floor of the skull, becoming finally converted into a compound gland-like organ.

The neural hypophysis, or hinder lappet of the hypophysis, on the other hand, develops ventrally as a process of the basal portion of the thalamencephalon, or hinder part of the fore-brain. At first composed of tissue of exactly the same character as the rest of the thalamencephalon, it becomes solid below and converted into indifferent tissue; the portion of the process which remains hollow, and forms the base of the infundibulum, alone retains a nervous structure. Kölliker records that in pig embryos of 3 centimetres in length longitudinal bundles of nerve-fibres pass into the developing neural hypophysis, or processus infundibuli as it is called, from the base of the thalamencephalon.

In most cases, especially in Mammalia and also in Dipnoi, the neural hypophysis becomes closely and almost inseparably connected with the oral hypophysis. Usually the *Anlage* of the oral hypophysis lies in the region of the mouth epiblast; in Petromyzon and Myxine it lies in front of and outside the mouth. The process by which it got into the mouth involution cannot be explained without numerous figures.

According to Dohrn, the oral hypophysis arises in Petromyzon as an invagination of epiblast in front of the mouth between the oral and nasal depressions. It grows towards the base of the infundibulum, and comes into close relationship with the end of the notochord, *i.e.* with a structure derived from hypoblast, while it approaches a special process of hypoblast itself, with which, however, in Petromyzon it does not fuse. In Myxine, although the development is unfortunately not yet known, we may assume that this fusion is effected, for in that animal it opens throughout life into the gut (see figure, *O.M.*).

In Ammocœtes it gives off a certain number of gland-follicles, which, according to Dohrn, become pinched off in the Petromyzon. While I am not yet quite convinced of the certainty of this latter point, I find, in Myxine, numerous small glandular follicles opening into the oral hypophysis. In Petromyzon and Myxine the neural hypophysis is present, and, as I believe, not rudimentary. It appears to supply nerve-fibres to the oral hypophysis.

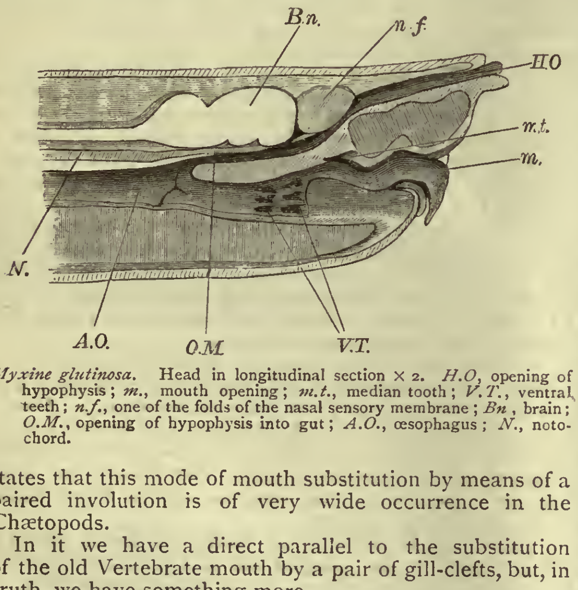
Dohrn finds in Hippocampus traces of a paired origin of the oral hypophysis. This is important.

I propose to divide the oral or glandular hypophysis into two parts, viz. a duct or main oral hypophysis and a glandular part or glandular hypophysis. The whole structure is without doubt in nearly all cases rudimentary, and of little or no functional importance. A mass of information bearing upon it has recently come to light in the study of the developmental history of Annelids, chiefly at the hands of Kleinenberg and Salensky.

From the results of Kleinenberg's work, more especially, we are placed in a position to compare the structure and development of the hypophysis with those of certain organs in the worms. To my mind, the comparison which follows is one of the neatest in the whole range of comparative morphology; I would therefore, before proceeding further, give a brief *résumé* of Kleinenberg's results so far as they here concern us.

In the first place, he records how the larval stomodæum or mouth is replaced in a very complicated manner by the Annelid permanent mouth or *Schlund*. The latter is formed as a paired involution of the stomodæum, *i.e.* of the epiblast, and this he considers to have originally represented stomodæal glands. It encroaches upon and swallows up the old mouth, and, finally fusing with the hypoblast, it opens into the gut.

The replacement of the larval mouth in Annelids by a new structure was already known, but Kleinenberg describes the steps of the process in great detail, and he



Myxine glutinosa. Head in longitudinal section × 2. *H.O*, opening of hypophysis; *m.*, mouth opening; *m.t.*, median tooth; *V.T.*, ventral teeth; *n.f.*, one of the folds of the nasal sensory membrane; *Bn*, brain; *O.M.*, opening of hypophysis into gut; *A.O.*, œsophagus; *N.*, notochord.

states that this mode of mouth substitution by means of a paired involution is of very wide occurrence in the Chætopods.

In it we have a direct parallel to the substitution of the old Vertebrate mouth by a pair of gill-clefts, but, in truth, we have something more.

Another phenomenon of extreme interest is the formation of the special mouth (or *Schlund*) nervous system. *This apparatus is only concerned with the innervation of the permanent* Schlund, *and takes no share in the innervation of the hypoblastic alimentary canal.* It arises as a special process of the hinder part of the subœsophageal ganglion: this grows towards the developing Schlund, becomes closely attached to the latter, fuses with it and gets pinched off from the larger portion of the subœsophageal ganglion, which is left as the first ganglion of the ventral chain.

I must here digress in order to discuss the question of the presence or absence of any representative of the supraœsophageal ganglion of Annelids in Vertebrates,[1] and here again Kleinenberg comes to our assistance.

I have myself devoted a good deal of attention to this point, and have arrived at the conclusion (held also, I believe, by Prof. Dohrn) that there is no likelihood at all of our finding an area in the Vertebrate brain which was ever pierced by the œsophagus—pierced so as to divide the brain into a supraœsophageal and a subœsophageal portion, which might be compared respectively to such divisions of the Annelidan nervous system. At first sight, this appears like an admission that the Annelidan theory of the origin of Vertebrates is untenable. But such is not the case.

From a large number of researches, including those of Bergh, Salensky, and Kleinenberg, we know that the supraœsophageal ganglion of Annelids certainly arises independently of the ventral chain, and that it only later becomes connected with the latter by the development of the circumœsophageal collar.

Kleinenberg's brilliant researches also teach us that the permanent Annelidan nervous system arises through substitution, and partial or entire disappearance of whole larval nervous apparatuses and sense-organs. And, indeed, after reading his beautiful work, one is fully prepared for one of the closing statements in it—that possibly the supraœsophageal ganglion is entirely absent in Vertebrates.

Personally, I have no hesitation at all in accepting this as probably true; but the grounds for my belief, or some of them, I can only hint at here. They arise out of as yet unpublished developmental researches. Briefly stated, I see in the development of the gill-clefts, with their special sense-organs and ganglia[1]—all of which lie in the region which is under the control of a system comparable to the ventral nerve-cord of Annelids—a probable cause of the disappearance of the supraœsophageal ganglion in the ancestors of Vertebrates,—in a similar way to that in which, according to Kleinenberg, the dislodging and destruction of the special larval ganglionic centres takes place in the Annelid.

I believe that in the ancestors of the Vertebrates, by the development of the eyes, and of the important gill sense-organs and ganglia, the ventral chain came to obtain control over a very extensive system of ganglia, sense-organs, and muscles; and, having already a control over the mouth or *Schlund*, it entirely deposed the supraœsophageal ganglion (and its sense-organs). The entire *raison d'être* of the latter being thus disposed of, it naturally degenerated and finally disappeared.

If it be admitted that the supraœsophageal ganglion of Annelids is absent in Vertebrates, and that the brain and spinal cord of the latter may be compared directly with the ventral cord of Annelids, then a whole host of direct structural relationships between Annelida and Vertebrates may be established. Kleinenberg expresses his opinion that the spinal ganglia of Vertebrates have their parallel in the parapodial ganglia of Annelids,—a comparison which, as I shall elsewhere show, is entirely justifiable for the spinal ganglia and for certain portions of the cranial ganglia also.

Let me now briefly review the conditions demanded of any structures in the Vertebrate which are to be homologized with the permanent mouth of Annelids. Such ought to arise as a paired involution of epiblast (though it is conceivable *a priori* that the paired character might be lost). This involution must fuse with, and open into, the cavity of the hypoblast. It must also give rise to certain glands, and it must have a special nervous system of its own derived from the hinder part of the first ventral ganglion or its homologue—which nervous system must supply it alone, and no other part of the alimentary canal.

All these conditions are fulfilled by the complex called hypophysis cerebri.

In at least one case (Hippocampus) the oral hypophy-

[1] I postpone the consideration of Prof. Semper's views on this point, and on the nature of the mouth in Annelids and Vertebrates.

[1] The cranial ganglia of Vertebrates are far more complicated morphologically than has hitherto been recognized. In addition to parts which appear to correspond morphologically to the posterior root ganglia of the spinal nerves plus the sympathetic ganglia, they also contain the special ganglia which are formed in connection with the gill sense-organs.

sis[1] is known to arise as a paired epiblastic involution (Dohrn). In the Cyclostomata it is formed as an epiblastic involution (possibly paired) at the extreme anterior end of the body. In one Vertebrate alone, Myxine (*vide* figure), it still opens into the hypoblast; in all others it approaches the hypoblast in development, but does not fuse with that layer. It always lies in very close relationship with the extreme end of the notochord—that is, with the end of a structure derived from the hypoblast.

In adult Petromyzon, in which the tube of the oral hypophysis has the same relationships as in Myxine, except that the posterior opening into the hypoblastic sac is absent, it nevertheless has an astonishing length, and ends blindly very close to the gut. In Myxine and Petromyzon, tubular glands are developed in connection with it. In all the higher Vertebrates, in which the oral part is very rudimentary, it always has a distinct glandular character.

And now, what of the last condition? This also is satisfactorily met. In all cases the oral hypophysis has a special, and indeed large, process of nervous matter (the processus infundibuli, or neural hypophysis), which is derived from the posterior part of the fore-brain, from the base of the infundibulum. This process is concerned with the innervation of the oral hypophysis alone. In Myxine and Petromyzon alone, so far as my researches extend (possibly also in Protopterus), this nervous system is not rudimentary. In most Vertebrates the neural hypophysis, which, as Kölliker aptly remarks, is at first composed of the same cell elements and fibres as the rest of the brain, degenerates, and in very many full-grown animals forms a mass of tissue, the structure of which many observers have compared to that of the suprarenal bodies (known to be masses of degenerated tissue).

The neural hypophysis is thus the most remarkable structure in the whole of the Vertebrate central nervous system. Though degenerated, it still clings to the traditions of its ancestry, for even, as it were, in its death it is closely and almost inseparably connected with the rest of the hypophysis, especially in Mammalia and in Dipnoi. In Myxine alone, of all Vertebrates, the old mouth still retains some of its functions as a mouth; it conducts the water of respiration to the gills. In this case, even, changes have occurred, for the nose[2] (see figure, *n.f.*) has got partly involved in the passage of the old mouth. If it be true that the nose was originally a branchial sense-organ—which view, in spite of Gegenbaur, I still maintain—its assumption of a position in the passage of the old mouth in Myxine is, on purely physiological grounds, intelligible.

It is well known that that which I call the old mouth in Myxine is purely respiratory, conducting water into the gills; and what then could be more likely than that one of the branchial sense-organs should be, as it were, told off to do duty at its entrance. It is certain, from Goette's and Dohrn's researches, that these passages in Myxine and Petromyzon are the representatives of the oral hypophysis. I have gone over and extended these observations, and can fully confirm Dohrn in nearly every point, and all I claim here is the identification of the hypoblastic opening in Myxine as the (modified) opening of the old mouth into the gut.

If the above morphological comparison can be maintained (and I believe it can), the importance of its bearing on the morphology of Vertebrates can hardly be over-estimated.

A number of other problems and conclusions arise out of all this, but I reserve the consideration of these for a much more exhaustive work, in which the literature of the subject will receive full attention. J. BEARD.

Anatomisches Institut, Freiburg i/B., November 16.

[1] I believe it is very frequently paired, though not at its point of origin.
[2] In Petromyzon, Dohrn finds that the nose is at first a special depression apart from the hypophysis invagination. The latter lies between the nose and mouth.

TIMBER, AND SOME OF ITS DISEASES.[1]

III.

HAVING now obtained some idea of the principal points in the structure and varieties of normal healthy timber, we may pass to the consideration of some of the diseases which affect it. The subject seems to fall very naturally into two convenient divisions, if we agree to treat of (1) those diseases which make their appearance in the living trees, and (2) those which are only found to affect dead timber after it is felled and sawn up. In reality, however, this mode of dividing the subject is purely arbitrary, and the two categories of diseases are linked together by all possible gradations.

Confining our attention for the present to the diseases of standing timber—*i.e.* which affect undoubtedly living trees—it can soon be shown that they are very numerous and varied in kind; hence it will be necessary to make some choice of what can best be described in this article. I shall therefore propose for the present to leave out of account those diseases which do injury to timber indirectly, such as leaf-diseases, the diseases of buds, growing roots, and so forth, as well as those which do harm in anticipation by injuring or destroying seedlings and young plants. The present article will thus be devoted to some of the diseases which attack the timber in the trees which are still standing; and as those caused by fungus parasites are the most interesting, we will for the present confine our attention to them.

It has long been known to planters and foresters that trees become rotten at the core, and even hollow, at all ages and in all kinds of situations, and that in many cases the first obvious signs that anything is the matter with the timber make their appearance when, after a high gale, a large limb snaps off, and the wood is found to be decayed internally. Now it is by no means implied that this rotting at the core—"wet-rot," "red-rot," &c., are other names generally applied to what is really a class of diseases—is *always* referable to a single cause; but it is certain that in a large number of cases it is due to the ravages of fungus parasites. The chief reason for popular misconceptions regarding these points is want of accurate knowledge of the structure and functions of wood on the one hand, and of the nature and biology of fungi on the other. The words disease, parasitism, decomposition, &c., convey very little meaning unless the student has had opportunities of obtaining some such knowledge of the biology of plants as can only be got in a modern laboratory: under this disadvantage the reader may not always grasp the full significance of what follows, but it will be at least clear that such fungi demand attention as serious enemies of our timber.

It will be advantageous to join the remarks I have to make to a part description of some of the contents of what is perhaps one of the most instructive and remarkable museums in the world—the Museum of Forest Botany in Münich, which I have lately had the good fortune to examine under the guidance of Prof. Robert Hartig, the distinguished botanist to whose energy the Museum is due, and to whose brilliant investigations we owe nearly all that has been discovered of the diseases of trees caused by the Hymenomycetes. Not only is Prof. Hartig's collection unique in itself, but the objects are classical, and illustrate facts which are as yet hardly known outside the small circle of specialists who have devoted themselves to such studies as are here referred to.

One of the most disastrous of the fungi which attack living trees is *Trametes radiciperda* (Hartig), the *Polyporus annosus* of Fries, and it is especially destructive to the Coniferæ. Almost everyone is familiar with some of our common Polyporei, especially those the fructifications of which project like irregular brackets of various colours from dead stumps, or from the stems of moribund trees;

[1] Continued from p. 207.

well, such forms will be found on examination to have numerous minute pores on the under side or on the upper side of their cheese-like, corky, or woody substance, and the spores which reproduce the fungus are developed on the walls lining these many pores, to which these fungi owe their name. *Trametes radiciperda* is one of those forms which has its pores on the upper side of the spore-bearing fructification, and presents the remarkable peculiarity of developing the latter on the exterior of roots beneath the surface of the soil (Fig. 11).

This is not the place to discuss the characters of species and genera, nor to enter at any detail into the structure of fungi, but it is necessary to point out that in those cases where the casual observer sees only the fructification of a Polyporus, or of a toadstool, or of a mushroom (projecting from a rotting stump or from the ground, for

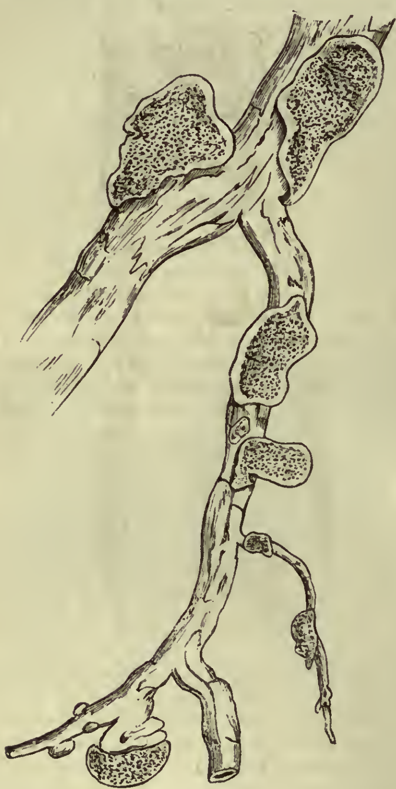


FIG. 11.—Portion of root of a spruce-fir, with fructification of *Trametes radiciperda* (after Hartig). Each fructification is a yellowish-white mass of felt-like substance spread over the root, and with minute pores, in which the spores are produced, on its outer surface; the mycelium which has developed it is in the interior of the root.

instance), the botanist knows that this fructification is attached to, and has taken origin from, a number of fine colourless filaments woven into a felt-like mass known as the mycelium, and that this felt-work of mycelium is spreading on and in the rotten wood, or soil, or whatever else the fungus grows on, and acts as roots, &c., for the benefit of the fructification.

Now, the peculiarity of the mycelium of this *Trametes radiciperda* is that it spreads in the wood of the roots and trunks of pines and firs and other Conifers, and takes its nourishment from the wood-substance, &c., and it is to the researches of Hartig that we owe our knowledge of how it gets there and what it does when there. He found that the spores germinate easily in the moisture around the roots, and put forth filaments which enter between the bark-scales, and thus the mycelium establishes itself in the living tree, between the cortex and the wood (Fig 12). It is curious to note that the spores may be carried from place to place by mice and other burrowing animals, since this Trametes is apt to develop its fructification and spores in the burrows, and they are rubbed off into the fur of the animals as they pass over and under the spore-bearing mass.

When the mycelium obtains a hold in the root, it soon spreads between the cortex and the wood, feeding upon, and of course destroying, the cambium. Here it spreads in the form of thin flattened bands, with a silky lustre, making its way up the root to the base of the stem, whence it goes on spreading further up into the trunk (Fig. 12).

Even if the mycelium confined its ravages to the cambial region, it is obvious, from what was described in Articles I. and II., that it would be disastrous to the tree; but its destructive influence extends much further than this. In the first place, it can spread to another root

FIG. 12.—Piece of root of spruce-fir, with the mycelium of *Trametes radiciperda* (after Hartig) enlarged about 3 times. The white mycelium spreads in a fan-like manner over the surface beneath the cortex, as seen in the figure where the latter has been lifted and removed (*a*). Here and there the mycelium bursts through the cortex in the form of white protuberances (*b*), to form the fructifications.

belonging to another tree, if the latter comes in contact in the moist soil with a root already infected; in the second place, the mycelium sends fine filaments in all directions into the wood itself, and the destructive action of these filaments—called hyphæ—soon reduces the timber, for several yards up the trunk, to a rotting, useless mass. After thus destroying the roots and lower parts of the tree, the mycelium may then begin to break through the dead bark, and again form the fructifications referred to.

Since, as we shall see, *Trametes radiciperda* is not the only fungus which brings about the destruction of standing timber from the roots upwards, it may be well to see what characters enable us to distinguish the disease thus induced, in the absence of the fructification.

The most obvious external symptoms of the disease in a plantation, &c., are: the leaves turn pale, and then yellow, and die off; then the lower part of the stem begins to die, and rots, though the bark higher up may preserve its normal appearance. If the bark is removed

from one of the diseased roots or stems, there may be seen the flat, silky, white bands of mycelium running in the plane of the cambium, and here and there protruding tiny white cushions between the scales of the bark (Fig. 12); in advanced stages the fructifications developed from these cushions may also be found. The wood inside the diseased root will be soft and damp, and in a more or less advanced stage of decomposition.

On examining the timber itself, we again obtain distinctive characters which enable the expert to detect the disease at a glance. I had the good fortune to spend several pleasant hours in the Münich Museum examining and comparing the various diseases of timbers, and it is astonishing how well marked the symptoms are. In the present case the wood at a certain stage presents the appearance represented in the drawing, Fig. 13. The general tone is yellow, passing into a browner hue. Scattered here and there in this ground-work of still sounder wood are peculiar oval or irregular patches of snowy white, and in the centre of each white patch is a black speck. Nothing surprised me more than the accu-

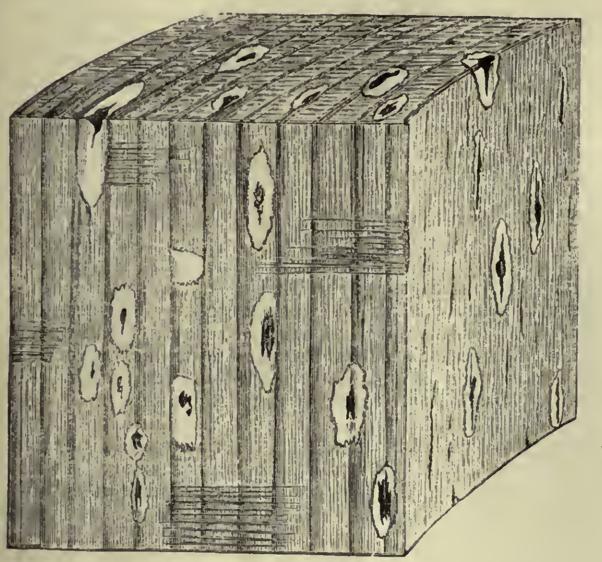

FIG. 13.—A block of the timber of a spruce-fir, attacked by *Trametes radiciperda*. The general colour is yellow, and in the yellow matrix of less rotten wood are soft white patches, each with a black speck in it. These patches are portions completely disorganized by the action of the mycelium, and the appearance is very characteristic of this particular disease. (After Hartig.)

racy with which Prof. Hartig's figures reproduce the characteristic appearance of the original specimens in his classical collection, and I have tried to copy this in the woodcut, but of course the want of colour makes itself evident.

It is interesting and important to trace the earlier changes in the diseased timber. When the filaments of the fungus first begin to enter the wood, they grow upwards more rapidly than across the grain, piercing the walls of the cells and tracheides by means of a secretion—a soluble ferment—which they exude. This ferment softens and dissolves the substance of the walls, and therefore, of course, destroys the structure and firmness, &c., of the timber. Supposing the filaments to enter cells which still contain protoplasm and starch, and other nutritive substances (such as occur in the medullary rays, for example), the filaments kill the living contents and feed on them. The result is that what remains unconsumed acquires a darker colour, and this makes itself visible in the mass to the unaided eye as a rosy or purple hue, gradually spreading through the attacked timber. As the destructive action of the fungus proceeds in the wood, the purple shades are gradually replaced by a yellowish cast, and a series of minute black dots make their appearance here and there; then the black dots gradually surround themselves with the white areas, and we have the stage shown in Fig. 13.

These white areas are the remains of the elements of the wood which have already been completely delignified by the action of the ferment secreted by the fungus filaments—*i.e.* the hard woody cell-walls have become converted into soft and swelling cellulose, and the filaments are dissolving and feeding upon the latter (Fig. 14). In the next stage of the advancing destruction of the timber the black dots mostly disappear, and the white areas get larger; then the middle-lamella between the contiguous

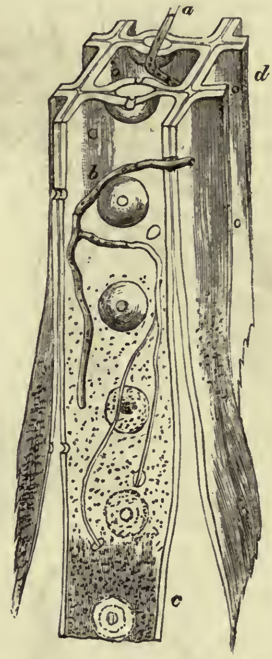

FIG. 14.—Sectional view of a tracheide of the spruce-fir, attacked by the hyphæ (*a*, *b*) of a *Trametes*, highly magnified (after Hartig). The upper part of the tracheide has its walls still sound, though already pierced by the hyphæ; the lower part (*c*) has the walls completely delignified, and converted into cellulose, which swells up and dissolves The middle-lamella is also undergoing diss lution. The holes in the walls have been bored by hyph e.

elements of the wood becomes dissolved, and soft places and cavities are produced, causing the previously firm timber to become spongy and soft, and it eventually breaks up into a rotting mass of vegetable remains.

It will readily be understood that all these progressive changes are accompanied by a decrease in the specific gravity of the timber, for the fungus decomposes the substance much in the same way as it is decomposed by putrefaction or combustion, *i.e.* it causes the burning off of the carbon, hydrogen, and nitrogen, in the presence of oxygen, to carbon-dioxide, water, and ammonia, retaining part in its own substance for the time being, and living at its expense.

H. MARSHALL WARD.

(*To be continued.*)

PROFESSOR ALEXANDER DICKSON.

THE close of 1887 has been marked by a long death-roll in the ranks of science. In the company of botanists it has been especially heavy, and now the sad news of the tragically sudden death of Prof. Alexander

Dickson, at the early age of fifty-one, comes upon us with startling unexpectedness. Two days before Christmas Prof. Dickson left Edinburgh, in his usual health and vigour, for Hartree House, his Lanarkshire residence. During the following days he spent much of his time in the favourite pastime of curling, which he much enjoyed. On Friday last, December 30, 1887, he was in exceptionally good spirits on the ice; his side was winning a close match, and he entered keenly into the excitement of the moment, when, without warning, he dropped dead in the act of making a shot.

Alexander Dickson was born in Edinburgh on February 21, 1836, the second son of David Dickson, of Hartree and Kilbucho, extensive estates in Lanarkshire and Peebles-shire, to which he afterwards succeeded, his elder brother having predeceased his father. Educated when a boy at home, he proceeded to the University of Edinburgh, where he graduated M.D. in 1860, obtaining a gold medal for a thesis on "The Development of the Seed-vessel of *Caryophyllaceæ*." After graduating, he soon abandoned medicine, and devoted himself to botanical pursuits. During the year 1862 he acted as Deputy Professor of Botany in the University of Aberdeen for Prof. Dickie, then in bad health; in 1866 he was appointed to the Chair of Botany in the University of Dublin, vacant by the death of Dr. W. H. Harvey; and a year later he added to this appointment that of Professor of Botany in the Royal College of Science for Ireland. In 1868, on the death of Dr. G. W. Walker-Arnott, he succeeded to the Chair of Botany in the University of Glasgow, which he held until 1879, when he was appointed Professor of Botany in the University, and Regius Keeper of the Royal Botanic Garden, in Edinburgh, upon the resignation of these offices by Dr. J. H. Balfour. He held these appointments at the time of his death. He received the honorary degree of M.D. from the University of Dublin, and that of LL.D. from the University of Glasgow, and was a member of various learned Societies. Besides his scientific life he had another important part to play as a laird with large properties in three counties, and he was a model landlord. He had the highest ideas of the duties of his position, and acted up to them. Money, time, and energy were given with self-denying devotion to the improvement of his farms and of the condition of his tenants, and no better-ordered estates could be found than those which he controlled. He was a Deputy-Lieutenant of Peebles-shire, and took an active share in all the functions which his position entailed.

By the death of Alexander Dickson the botanical world loses one of its best morphologists. He wore the mantle of the old French school typified in Mirbel, Richard, St. Hilaire, and Payer, of which Baillon is at present the foremost French representative; and at a time like the present, when it is a fashion to decry morphology, his loss falls all the more heavily. No botanist in this country had so full and accurate a grasp of organography. His published papers, numerous and valuable as they are, afford but an imperfect idea, significant indeed, of the wealth of his knowledge, and the keenness of his perception. Those who came in contact with him will remember the fascination of his discourse, and the surprising variety and aptness of the illustrations which he could bring up one after the other to support his own views or confound those of an opponent. In all his scientific work the strong conservatism of his nature found expression. His cautious and logical mind did not allow of his following with enthusiasm rash speculations of the more ardent botanical workers; and the flood of literature on botanical subjects which is poured out year by year had no terrors for him, as he acted upon the principle, which many will agree is a sound one, that, if you leave the literature until it is a year or two old, what is worth reading sifts itself. The soundness of his judgment upon scientific problems may in some measure be traced to the influence of the precept and example of that glorious band of real teachers, which at the time of his University career made Edinburgh a centre of attraction in the intellectual world; and a good illustration of his force of mind is to be found in his attitude towards the much-discussed question of the growth of the cell-wall. Having satisfied himself that the apposition theory was a sufficient explanation, he consistently opposed Nägeli's intussusception theory during the years when it was all but universally accepted; and now the botanical world has come round again to regard an apposition theory as that which has the better basis in fact.

All organographic questions had a peculiar interest for Dickson. A considerable portion of his own work was devoted to the elucidation of the true nature of the flowers in *Coniferæ*. As the result of his researches on *Dammara* and observations on other *Coniferæ*, he adopted Baillon's view of the carpellary nature of the integument in *Pinus*, and, notwithstanding the defection by Strasburger, who originally supported this view, he continued to maintain it. Phyllotaxis was a subject to which he devoted great attention, and upon which he published several important papers. Amongst his most valuable researches are those on the embryogeny of *Tropæolum*, in which he traced the history of the peculiar roots by which the embryo is nursed in the seed; and the records of his embryological researches in *Pinguicula*, *Ruscus*, *Zostera*, *Phœnix*, *Delphinium*, and other plants, are very interesting and valuable contributions to knowledge. In recent years he gave considerable attention to the construction and development of pitcher-plants, and proved the true nature of the parts of their complex organs; and the structure of the *Hepaticæ* also engrossed him, one of his last papers being upon some species of this group, in which he joined issue with Leitjeb upon some fundamental points. In all his work there may be seen the scrupulous accuracy and attention to detail which was a leading feature in his character, and no man ever worked with more care and jealous regard for truth and with a more generous appreciation of the work of others.

Amidst the work of his scientific life and the duties connected with his estates he found time to cultivate the artistic side of his nature, which was developed in no ordinary degree. He was an accomplished and enthusiastic musician, and in later years found peculiar pleasure in collecting Gaelic airs. At botanical excursions to the Highlands he might be frequently found noting down an air as it was droned by a gillie or whistled by a herd, and he amassed a considerable number of these airs, which at one time he thought of publishing. He was also a very skilful draughtsman, and his drawings in chalk on the slate were quite a feature of his lectures.

In the discharge of every duty he was most conscientious, and his unostentatious kindliness attracted everyone who had dealings with him. Quiet and retiring in disposition, he was endeared to all by the nobility of his character and his sympathetic nature. As Professor his students loved him; as laird his tenants loved him. It has been said of him he could never lose a friend, for he never could say an unkind word or omit to do a kind action, and in this estimate all who knew him will concur. The news of his death will be heard with sorrow by a wide circle of friends, and bring sadness to many a heart which will mourn for one who had fine generosity of the kind that lets "not the right hand know what the left hand doeth."

NOTES.

THE Municipal Council of Paris proposes to establish in the Faculty of Sciences a new professorship devoted to the philosophy of biology, and especially to the teaching of the doctrines of Darwin. This distresses some of the older French zoologists,

but "their reign," a correspondent writes to us from Paris, "is coming to an end, and notwithstanding their obstinate and unintelligent opposition, Darwinism is the creed of all the younger French naturalists. The only trouble with regard to the new professorship will be to put the right man in the right place."

PROF. BONNEY'S course of lectures on geology begins at University College on Wednesday, January 11, and will be continued on the Thursdays, Tuesdays, and Wednesdays following. The course on economic geology begins on the following Friday, and will be continued on that day in each week.

A COURSE of about six lectures on "Photographic Chemistry" will shortly be delivered by Prof. R. Meldola, F.R.S., at the Finsbury Technical College. The course will begin on Wednesday, January 18, at 7.30 p.m., and be continued on successive Wednesdays. The object of the lecturer will be to develop the scientific principles upon which modern photography is based, so as to enable professional and amateur photographers to keep abreast of recent advancements in the subject. Those who attend the lectures will have the opportunity, if they desire it, of receiving practical laboratory instruction in the testing and valuation of photographic chemicals.

AT the opening meeting of the session of the Society of Telegraph-Engineers and Electricians, on Thursday, the 12th instant, the new President, Mr. Edward Graves, will deliver his inaugural address.

IN the abstracts of the Proceedings of the Chemical Society (Jan.–Dec. 1887) we find the following list of grants made from the Research Fund of the Society during the year:—£25 to Prof. E. H. Rennie, for the further study of the red colouring-matter of *Drosera whittakeri*; £25 to Mr. Holland Crompton, for the study of the action of nitric acid on copper-zinc and copper-tin alloys with the object of determining whether the metals exist in combination or admixed; £10 to Mr. C. H. Bothamley, for experiments on the use of dyes in photography, and especially on the sensitizing action of the dye; £25 to Mr. W. P. Wynne, for the determination of the nature of the products formed on oxidizing nitric oxide by admixture with oxygen; £10 to Mr. A. Wynter Blyth, for the study of the constitution of butter-fat.

METEOROLOGY is indebted to Dr. J. Hann for an exhaustive discussion of the distribution of atmospheric pressure over Central and Southern Europe, based upon the monthly and yearly means at 205 stations, for the thirty years 1851–80. Very few such discussions have been undertaken since the appearance of Buchan's great work, about twenty years ago. The author insists on the application of the correction for gravity, which up to the present time has been generally neglected. Only a few observations for France have been used in this discussion, but a work of a similar nature is in hand for that country by M. Angot. Charts are also drawn for each month and for the year, showing the isobars for every ·02 inch at the sea-level, and also for four months and the year at the level of 500 metres above the sea. The work forms Part 2, vol. ii. of Dr. Penck's "Geographische Abhandlungen" (Vienna, 1887).

THE Chief Signal Officer of the United States has issued a circular, dated December 6, stating that as, in his belief, the great value of simultaneous maps consists in showing the general features of the weather of the northern hemisphere, he has decided to reproduce daily a chart showing the general outlines of the pressure and wind for certain selected stations, although as before stated (NATURE, Dec. 8, p. 137), he cannot guarantee their continuance for any great length of time. The charts have commenced with October 1, 1886, and are based on the observations taken at noon, Greenwich time; the temperature observations are not represented, owing to the limited means available for such work.

THE Central Physical Observatory of St. Petersburg has issued a very useful table, showing for all its telegraphic stations the normal temperatures for 7 a.m. for each month, calculated from the number of years available for each place. From these values the Observatory constructs diagrams showing the annual march of the temperature, and from these curves the normal temperature may be calculated very closely for each day of the year. These data enable the Observatory to introduce into its Daily Weather Reports the departure of the temperature day by day from its normal value. The normal temperatures for foreign stations are to be similarly dealt with subsequently.

THE Swedish Government has given notice that in the beginning of the year 1888, a fog signal will be established near Hallands Wäderö lighthouse, on the eastern shore of the northern approach to the Sound, Kattegat. The signal will be a steam syren, which, during thick or foggy weather, will give *two blasts every minute*, in the following manner; a low note of *seven seconds* duration, an interval of *three seconds* silence, then a high note of *three seconds* duration, followed by an interval of *forty-seven seconds* silence.

THE Government *Gazette* of the Colony of Lagos of July 30 last contains monthly meteorological means for the year 1886. The observations are made at the Colonial Hospital, lat. 6° 27′ N., long. 3° 26′ E.

ON December 11, about 5.30 p.m., a brilliant meteor was seen in and around Christiania. It moved slowly in a south-easterly direction, and disappeared behind a bank of clouds. Its light, of a yellow-green colour, was very intense. The passage occupied about five seconds.

EARTHQUAKES on December 16 and 17 are reported from Prinpolje and Plewlje, in Bosnia. At Werny, in Turkistan, a shock occurred at midnight on December 16. A shock was noticed at Geneva on December 19 between 5 and 6 p.m. A telegram from Mexico states that a sharp shock occurred there at half past 7 on January 2.

A NUMBER of highly interesting experiments upon the behaviour of passive iron towards nitric acid when placed in a powerful magnetic field have recently been made by Messrs. Nichols and Franklin (*Amer. Journ. of Science*, December 1887). About 8 cubic centimetres of nitric acid, specific gravity 1·368, were poured upon a gramme of powdered iron contained in a perfectly clean test-tube. This test-tube was immersed in water contained in an outer glass vessel, and the temperature of the contents of the tube could be accurately ascertained by means of a thermometer suspended in it. The whole apparatus was then carefully arranged between the poles of an electro-magnet specially constructed to give a field as uniform as possible. Before actuating the magnet it was found that the iron remained perfectly passive in presence of the nitric acid until the temperature was raised to 89°, when the usual explosion consequent upon loss of passivity occurred. But on repeating the experiment when a powerful current was traversing the coils of the electro-magnet, effervescence commenced at once, and at 51° the explosion occurred in a most violent manner, projecting most of the liquid out of the tube. The remainder of the liquid, however, remained quiescent until the iron was touched with the thermometer-bulb, when a second explosion occurred. In a third experiment the magnet was not actuated until the apparatus was heated to 60°; but the moment the current was allowed to pass the explosion

occurred instantaneously. Hence it appears that the action of the magnet is to lower the temperature of transition from the passive to the active state. In attempting to determine the cause of this singular phenomenon, it was found that when two iron bars placed parallel to the lines of force in the magnetic field were submerged in any liquid capable of attacking iron, the ends of one bar and the central portions of the other being alone allowed to come into actual contact with the liquid, the bar with ends exposed became in relation to the other as zinc to platinum, so that on connecting the bars by wires a permanent current was found to flow. Hence it is supposed that, in case of a single mass of iron, local currents will be set up between those parts in which magnetic poles are induced and the intermediate parts, and Messrs. Nichols and Franklin are of opinion that these local currents are the cause of the curious behaviour of passive iron in the magnetic field.

A MEETING was held at Philadelphia on December 12 to celebrate the hundredth anniversary of the birth of Thomas Hopkins Gallaudet, the pioneer of the movement for the instruction of the deaf in America. A short biographical sketch of Gallaudet was read, and one of his poems was recited by four deaf girls in the sign-language. Prof. Graham Bell delivered an address, which was interpreted into the sign-language as rapidly as it was spoken, and, according to *Science*, was greatly appreciated by the many deaf persons in the audience. The two sons of Gallaudet, both of whom are engaged in continuing the work of their father—one as the President of the deaf-mute College at Washington, the other as a pastor for the deaf—were present, and made remarks suitable to the occasion.

MESSRS. MACMILLAN AND CO. will publish immediately a new Treatise on Algebra, by Mr. Charles Smith, of Sidney Sussex College, Cambridge, whose previous text-books on Conic Sections, on Solid Geometry, and on Elementary Algebra have been very favourably received. The new book is designed for the use of the higher classes of schools and the junior students in the Universities. One important change is made from the usual order adopted in English text-books on algebra, in that some of the tests of the convergency of infinite series are considered before such series are made any use of. A knowledge of the elementary properties of determinants being of great and increasing practical utility, Mr. Smith has introduced a short discussion of their fundamental properties, founded on the treatises of Dostor and Muir. No pains have been spared to insure variety and interest in the examples, which have been selected from numerous examination-papers and from the mathematical journals.

MESSRS. MACMILLAN AND CO. have in the press a treatise on Higher Arithmetic and Elementary Mensuration, by Mr. P. Goyen, Inspector of Schools in New Zealand. Feeling the defect in most text-books of arithmetic that the worked-out types are all of the simplest character, while the exercises which follow them abound in difficulties, Mr. Goyen has worked out an immensely large number and variety of graduated types, and taken great pains to adapt the exercises to them. In the mensuration, wherever the geometrical proof of a rule is quite simple, it is given. A chapter on surds is inserted, because a knowledge of surd operations is useful in mensuration, and is required in many public examinations.

A GOOD address on some sociological aspects of sanitation was lately delivered before the Philosophical Society of Glasgow by Dr. James B. Russell, President of the Society. This address has now been published. It contains some excellent remarks on the extent to which the State has a right to limit individual freedom in the attempt to establish the conditions of public health.

THE Journal of the Straits Branch of the Royal Asiatic Society (No. 18), just received, contains the Malay text, with an English translation, of "Raja Donan," a Malay fairy-tale. This is one of a series of *cheritras*, taken down, word for word, from the lips of Mir Hassan. Among the other contents of the number are an essay (continued from No. 17) towards a bibliography of Siam, and an English, Sulu, and Malay vocabulary.

THE editorship of the well-known Brunswick scientific journal, *Globus*, changed with the new year, or, rather, with the commencement of the fifty-third volume on December 19. Dr. Emil Deckert takes the place of Dr. Richard Kiepert, and at the same time an alteration is made in the sub-title. Where, formerly, this read, "*mit besonderer Berücksichtigung der Anthropologie und Ethnologie*," it now reads "*mit besonderer Berücksichtigung der Ethnologie, der Kulturverhältnisse, und des Welthandels*," and in an address to the reader the editor and publishers explain that the alteration represents a corresponding alteration in the programme. As before, every effort will be made to supply abundant information of a geographical and ethnological character; but as German national interests have largely developed and extended in the last few years, in future a good deal more attention will be devoted to questions connected, as we understand it, with German possessions and German interests abroad. The practical effects of thus enlarging the scope of the journal are not apparent in the number before us, but it may be hoped that *Globus* will not lose its character as a popular educator in geography and the allied subjects. Why a similar journal has not been established in this country is a mystery.

AN American journal devoted to geology and the allied sciences has just been started. It is called the *American Geologist*, and will for the present be published at Minneapolis, Minn.

MR. A. SIDNEY OLLIFF, of the Australian Museum, Sydney, writes to the January number of the *Entomologist* about giant Lepidopterous larvæ in Australia. The larva of *Chalepteryx collesi*, a large moth which was unusually abundant during the past summer in the vicinity of Sydney, often, he says, attains the length of 7 inches, and is robust in proportion. This moth feeds on various Eucalypti, and is of a rich satiny-brown colour; each segment, except the first, is furnished with eight yellow verrucose spots, which emit long brown bristles; the anal extremity, a yellow band on the first segment, and two additional verrucose spots on the second and third segments also give rise to bristles. The cocoon, as well as the larva of this species, is armed with fine and exceedingly sharp bristles, which, if carelessly handled, readily penetrate the skin, causing considerable irritation. The larva of the beautiful swift (*Zelotypia stacyi*) measures 8 inches when full grown, and Mr. Olliff has seen several *Cossus* larvæ of similar dimensions.

IN the *Entomologist* for January, Mr. Alfred Bell offers some suggestions about post-Glacial insects. So far as his experience goes, insect remains are by no means common, and belong chiefly to the Coleoptera. He gives thirty species, nearly all of which belong to this division of the insect world. As Mr. Bell points out, however, it does not follow that Lepidoptera were not present during the post-Glacial period, since they occur in beautiful preservation in deposits of much older date in England and on the Continent. The nature of the post-Glacial soils was not favourable to the preservation of soft-bodied animals. "Hence," says Mr. Bell, "if anyone knows of Lepidoptera retained in a fossil state, it will be of real service to science if he will say where they were found, and under what conditions."

IN the January number of the *Zoologist*, Mr. Allan Ellison has an interesting article on the autumnal migration of birds in Ireland. He says that the migration movement of last autumn

in Ireland was in all respects a most exceptional one. Some of the migrants appeared unusually early, and all in much larger numbers than Mr. Ellison had ever before observed. On October 8 he saw the first flocks, both of starlings and redwings. On the same day, and for about a week after, immense numbers of golden plovers were passing over, flying towards the west and south-west in large V-shaped strings. This was about the usual time for starlings and redwings, but early for golden plover. On the 11th again both redwings and starlings were constantly passing. On the 16th he observed a great host of fieldfares, many thousands in number, winging their way across the sky towards the south-west. From October 17 to the beginning of November the starling migration was at its height, the flocks being much larger and more numerous than he had ever observed in former years. He saw four within a quarter of an hour on the afternoon of the 18th. At 4 p.m. on the 22nd, the largest flock he ever saw passed over. It was in the form of a column, perhaps nearly a mile long, and must have numbered thousands, spanning the sky from horizon to horizon for more than half a minute, and was followed in a short time by two smaller flocks. All the latter part of October skylarks were from time to time flying over, generally large straggling flocks or scattered individuals, flying nearly out of sight, but their call-notes being distinctly audible. Mr. Ellison hopes that those who are favourably situated for observing the arrival of winter birds will report whether they have noticed a corresponding abundance of migrant this season.

THE new number of *Mind* opens with an able and suggestive article on pleasure, pain, desire, and volition, by Mr. F. H. Bradley. Mr. J. McK. Cattell has an interesting paper on the Psychological Laboratory at Leipzig. Mr. T. Whittaker writes on individualism and State action; and Mr. D. G. Ritchie on origin and validity.

PARIS is soon to have a Museum of Religions. M. Guimet, of Lyons, who has been a great traveller, has been engaged for years past in collecting altars, priests' robes, and other objects relating to religious ceremonies. These objects he presented some time ago to Paris on condition that a building should be specially devoted to them. This building, close to the Trocadéro Palace, has just been finished, and the collection will soon be transferred to it.

THE additions to the Zoological Society's Gardens during the past week include two Spotted Ichneumons (*Herpestes nepalensis*), a —— Fox (*Canis* ——) from Afghanistan, presented by Lieut.-Colonel Sir Oliver B. C. St. John, K.C.S.I.; a Common Otter (*Lutra vulgaris*), British, presented by Mr. Edward Hart; a Red-throated Diver (*Colymbus septentrionalis*), British, presented by Mr. Charles A. Howell; two Greater Sulphur-crested Cockatoos (*Cacatua galerita*) from Australia, presented by Master Rankin.

OUR ASTRONOMICAL COLUMN.

BRAZILIAN RESULTS FROM THE TRANSIT OF VENUS.—M. Cruls, in a note to the Paris Académie des Sciences, states that the reports of the various expeditions sent out by the Brazilian Government to observe the transit of Venus in 1882 are almost entirely printed, and will shortly appear. Three stations were occupied, viz. S. Thomas in the Antilles, Olinda in Brazil, and Punta-Arenas in the Straits of Magellan. The Baron de Teffé was in command of the first expedition; M. J. d'O. Lacaille of the second, and M. Cruls himself of the third. The duration of the transit at Punta-Arenas was nearly the mean duration, both ingress and egress being slightly accelerated. The two more northern stations had the duration much shortened, ingress being retarded, and egress accelerated. The chief observer at each station was supplied with an equatorial of 6·3 inches aperture; and at S. Thomas two other telescopes of 4·5 and 4·1 inches respectively were also used. At Olinda likewise there was a second telescope in use, of 4·5 inches aperture. The method of projection was employed in order to get rid of the physiological effects produced by the intensity of the solar light, and in combining the observations made with telescopes of different apertures, weights were given to them proportional to the square of the diameters of the object-glasses, in accordance with the results obtained from the experiments of MM. Wolf and André. The resulting parallax from the internal contacts is 8″·808.

THE ASTEROIDS.—Prof. Daniel Kirkwood, of the Indiana University, has just issued a short essay on the asteroids or minor planets, this group of tiny bodies being entitled on many grounds to more particular consideration than it has yet generally received. The first part of the essay gives a brief sketch of the history of the discovery of the first five asteroids, together with the names of the discoverers and date of discovery of all as yet known to us, and a table giving the elements of their orbits. Prof. Kirkwood makes it clear that the numbers of those still unknown are practically inexhaustible, for if Leverrier's estimate be correct, that the quantity of matter contained in the group cannot be greater than one-fourth the mass of the earth, it would yet require no fewer than 72,000,000 bodies as large as Menippe to make up this amount. Fortunately the rate of discovery appears limited to ten or a dozen per annum, so that there is no immediate danger of our being overwhelmed by the impossibility of following up some few millions of orbits. The second part of the work deals with questions relating to the origin of the group, and with certain relationships apparent in their orbits, particularly with regard to the irregular distribution of the asteroids in their ring, certain districts being left entirely void, viz. those where the asteroid would have a period commensurable with that of Jupiter. Prof. Kirkwood has on former occasions repeatedly shown how Jupiter would tend to eliminate bodies revolving in these positions by increasing the eccentricities of their orbits until their perihelion distances fell within the body of the sun itself, and he has accounted for the gaps in the ring of Saturn upon a similar principle. Prof. Kirkwood is of opinion that several of our periodic comets may have been originally members of the asteroid family. All the thirteen comets whose periods correspond to mean distances within the asteroid zone have direct motion, and inclinations similar to those of the minor planets, and their eccentricities are generally less than that of other known comets; whilst five of these comets have periods respectively corresponding to some of the most marked gaps in the asteroid zone.

Prof. Kirkwood makes no reference to the importance of certain members of the group as affording means for the determination of the solar parallax, which many astronomers will consider to be their most useful function, and as compensating for the enormous labour, both of observation and computation, involved in following the paths of so great a number of wanderers. And it would have been exceedingly useful if he had supplemented his other tables by one showing those asteroids which have only been observed during one opposition. Some of those theoretically the most interesting have not been observed for several years, and are practically lost to us, and it would seem a matter of more pressing importance at the present time that these should be picked up again, if possible, rather than fresh additions should be made to a list already unmanageably long.

OLBERS' COMET.—The following ephemeris for Berlin midnight, by Dr. Krueger (*Astr. Nach.* No. 2818), is in continuation of that given in NATURE for 1887 December 15:—

1888.	R.A. h. m. s.	Decl. ° ′	Log *r*.	Log Δ.	Brightness.
Jan. 6	16 50 20	1 22·7 S.	0·2486	0·3821	0·45
8	16 54 8	1 43·4 S.			
10	16 57 51	2 3·4 S.	0·2583	0·3854	0·43
12	17 1 29	2 23·6 S.			
14	17 5 3	2 41·2 S.	0·2679	0·3884	0·40
16	17 8 31	2 59·2 S.			
18	17 11 55	3 16·6 S.	0·2773	0·3910	0·38
20	17 15 14	3 33·4 S.			
22	17 18 29	3 49·6 S.	0·2866	0·3932	0·36

The brightness on August 27 is taken as unity.

Dr. E. Lamp succeeded in seeing the comet for a short time on December 12, and concludes, from a very rough comparison with a star that the ephemeris then required a correction of + 8s. in R.A., but was practically right in Decl.

THE CLINTON CATALOGUE.—The *Sidereal Messenger* for December announces that the great catalogue of 30,000 stars, upon which Dr. Peters and his assistant, Prof. Borst, have been engaged for several years past, is virtually completed, and ready for the press, and its publication is expected during the present winter. In the prosecution of this work Prof. Borst has gathered the stars from the various astronomical publications of the last fifty years, and reduced them to the epoch of the forthcoming catalogue.

OCCULTATIONS OF STARS BY PLANETS.—Herr A. Berberich calls attention in the *Astronomische Nachrichten*, No. 2814, to the importance of observations of occultations of stars by the planets, and supplies a list of stars which may possibly be occulted by either Venus, Mars, Jupiter, or Saturn, during the course of the present year. Such observations have been extremely rare, yet they would prove extremely important, for they would throw light on the extent and density of the planetary atmospheres, and would afford a means in the cases of Mars and Venus for the determination of parallax and diameter. Herr Berberich adds that in the case of the three outer planets the occultation of a star by the primary would afford a specially favourable opportunity for the determination of the positions of the satellites, since micrometer measures of their places as referred to the occulted star would be free from many errors to which the direct comparison of the planet and its satellites is exposed.

The following stars may possibly undergo occultation during the next fortnight:—

Planet.	G.M.T. of Conjunction in R.A.	Star.	Mag.	Pl − ✱ Δδ	Max Duration.
	h. m.	°		′	m.
♀	Jan. 5 16 29·2	S.D. −17 No. 4187	9·7	−0·13	6·0
♀	9 18 1·4	18 4279	9·5	+1·05	5·8
♂	12 3 41·4	4 3445	9·3	−0·18	7·4
♀	12 8 32·3	19 4401	9·3	+0·84	5·7
♀	14 18 40·8	19 4441	9·5	−0·19	5·6
♀	15 1 31·9	20 4446	9·5	+0·38	5·5
♀	17 23 22·5	20 4635	9·3	−0·57	5·4

The maximum duration is the interval between immersion and emersion for a central occultation.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *JANUARY* 8–14.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 8

Sun rises, 8h. 7m.; souths, 12h. 6m. 49·1s.; sets, 16h. 7m.: right asc. on meridian, 19h. 16·8m.; decl. 22° 17′ S. Sidereal Time at Sunset, 23h. 18m.

Moon (New on January 13, 9h.) rises, 2h. 14m.; souths, 7h. 34m.; sets, 12h. 44m.: right asc. on meridian, 14h. 43·4m.; decl. 10° 21′ S.

Planet.	Rises.	Souths.	Sets.	Right asc. and declination on meridian.	
	h. m.	h. m.	h. m.	h. m.	° ′
Mercury..	7 55	11 40	15 25	18 50·0	24 27 S.
Venus.....	4 36	9 1	13 26	16 10·3	18 29 S.
Mars......	0 11	5 53	11 35	13 1·9	4 14 S.
Jupiter....	4 16	8 38	13 0	15 47·4	19 4 S.
Saturn....	17 28*	1 19	9 10	8 27·1	19 39 N.
Uranus...	0 23	5 55	11 27	13 4·3	6 8 S.
Neptune..	12 51	20 31	4 11*	3 42·5	17 56 N.

* Indicates that the rising is that of the preceding evening and the setting that of the following morning.

DUNÉR ON STARS WITH SPECTRA OF CLASS III.[1]

I.

IN publishing a few days before his death the last part of his discoveries relating to the spectra of stars of the third class, D'Arrest pronounced the opinion that henceforward there would be nothing essential to add to the knowledge then possessed of the stellar spectra of this class in the northern heavens. When D'Arrest died, 123 well-developed objects of Class III.*a* were known, and counting all the objects known, 150; the stars known in Class III.*b* were 23. Actually, the well-developed stars of III.*a* are 214, and if all are reckoned, 475; the stars of III.*b* are 55 at least.

The number of objects in Class III. with which we are acquainted has been tripled by recent researches, but, besides, the relation between the numbers of the stars in the two lower classes has been considerably altered, considering that at present there are 8·5 stars III.*a* instead of 6·5, to 1 star III.*b*. However, we should commit a serious error if we drew the conclusion that in reality the spectra III.*b* were not more than nine times rarer than III.*a*. On account of the enormous width of the bands, one is able without any difficulty to recognize the nature of a spectrum III.*b* in very faint stars, which one is not able to do in III.*a*, unless in the rare objects of this class in which the bands are more marked and broader than usual.

I find this opinion confirmed by the fact that the researches of M. Vogel give more than 200 new spectra III.*a*, and have scarcely led to an acquaintance with one new spectrum III.*b*. It is very probable therefore that we are already acquainted with all these stars to the magnitude of 7·5 inclusive; this is rendered still more probable by the following table, which gives the number of the stars III.*a* and III.*b* belonging to different magnitudes:—

Magnitude.	Class III.*a*. Observed.	Class III.*a*. Calculated.	Class III.*b*. Observed.	Class III.*b*. Calculated.
1·0–1·9	2	1	0	0
2·0–2·9	5	3	0	0
3·0–3·9	9	11	0	0
4·0–4·9	31	28	0	1
5·0–5·9	88	90	2	2
6·0–6·9	134	380	11	8
7·0–7·9	151	—	18	24
8·0–8·9	37	—	14	—
9·0–9·9	18	—	10	—

[1] We have already referred generally to M. Dunér's important memoir published in the Transactions of the Swedish Academy. We now give a translation of his general conclusions.—ED.

In the columns headed "Calculated" are the numbers obtained by multiplying by 4/3 the numbers of the stars in the classes of different magnitude given in the "Wunder des Himmels," by Littrow, 5th ed. p. 577, deduced from the *Durchmusterung* of Argelander, and then dividing the result by 15 and 750 respectively. For the stars III.*a* the agreement is almost perfect up to the magnitude of 5·9 inclusive, and for III.*b* up to 6·9; up to 7·9 the agreement is pretty good, whilst after that the numbers observed are more and more in arrear of the numbers obtained by calculation. We may conclude therefore that our knowledge of the spectra III.*a* is almost complete up to the magnitude of 5·9 inclusive, and of spectra III.*b* up to 7·5 inclusive. The researches of M. Vogel have not added any new star III.*a* with a magnitude higher than 5·0, and only very few between 5·0 and 6·0, and, as I have already said, no new star III.*b* above the magnitude 7·5, although he has examined all the stars up to this limit of magnitude between − 2° and + 20° of declination. As to the difference existing between "observation" and "calculation" in the case of the III.*a* feebler than 6·0, we must remember that as yet no systematic spectroscopic research has been made of the stars between − 2° and − 23°, nor between + 20° and the North Pole. Consequently the number of stars III.*a* between 6·0 and 7·5 will probably be much increased before very long, and will approach the theoretic number. On this account I imagine the stars of III.*b* are fifty times rarer than those of III.*a*.

The list of these rare stars is probably already very complete for that part of the sky visible in Europe, for the nearer the researches of an astronomer are to the present time the feebler are the stars with spectra of this class which he discovers (Secchi 6·7, D'Arrest 7·0, Vogel 7·1, Duner 8·3, Pickering 9·1). The conclusions, therefore, which we can draw as to the manner in which these stars are distributed over the heavens deserve some confidence. Such a research is very interesting. We have already seen that the principal bands in these spectra owe their origin to the presence of a carbon compound in the atmosphere of the stars. It is important to know whether there is a certain direction in the heavens in which these stars are more numerous than in others, especially when we consider that the same substance is present in comets, which come from interstellar space. I have made such a research, and have come to the conclusion that the objects in question are grouped similarly to stars in general, being closer together in the neighbourhood of the Milky Way. Setting out from the position of the Pole of the Milky Way given by Heis, R.A. = 12h. 42m., Decl. = + 26° 8′, for the equinox 1900·0, I have calculated the quantities P, or the distances of the stars from this Pole, given in my catalogue. But to have my list a little more complete for the part of the heavens invisible in Europe, I have calculated the same quantity also for the following stars, whose spectra have been examined by M. Pechülé ("Expédition Danoise pour l'Observation du Passage de Venus," 1882, pp. 40–43).

Star.	Magnitude.	R.A. 1900·0. h. m.	Decl. 1900·0. ° ′	P. °
65 Schj.	8	5 40	−46 30	60·6
103 Schj.	8	7 54	−49 43	80·6
125	7·5	9 51	−41 7	78·6
126	8·5	9 57	−59 45	87·0
128	7	10 8	−34 30	71·5
130	6·5	10 31	−39 3	72·6

By the help of the P's found, I have obtained the following table, which indicates the numbers of those stars which are between the different limits of distance of the Poles, boreal or austral, of the Milky Way.

Limits of Polar Distance. ° °	No. of Stars.	Mean Magnitude.
0–35	3	6·6
35–60	8	6·6
60–70	8	7·2
70–80	13	7·4
80–90	29	8·3

It is at once seen that there is an immense accumulation between 80° and 90° of polar distance, and that the polar regions are totally empty up to 19° distance from the Pole; and this relation would doubtless become still more striking if our knowledge of these stars which are invisible in Europe was more complete; for, whilst the two Polar regions are for the most part visible, a great part of the Milky Way is always below our horizon. Besides the number of stars in the different zones, I have also calculated their mean magnitudes, and it will be seen that for them, as well as for other stars, there is this rule—that in the Milky Way the faint stars are much closer together than in the neighbourhood of its Poles.

One might perhaps suppose that there is a certain portion of the Milky Way where the stars III.*b* are more frequent than elsewhere. In order to decide this it is necessary first to calculate for each star the quantity which has the same relation to the Milky Way as the right ascensions have to the equator; and then make a table, on the distribution, having this quantity as its foundation. Such a research cannot, however, lead to good results as long as our acquaintance with the stars between 25° of south declination and the South Pole is almost *nil*. I will only say, then, that there is a great number of these stars around R.A. 305°, Decl. + 40°, but almost an equal number around R.A. 85°, Decl. + 25°. Now both these points are precisely those in which, in the northern hemisphere, the stars are closest together. It seems that they are grouped almost according to the same laws as all other stars, and that, properly speaking, there is no region where stars of the Class III.*b* abound.

A similar research of the stars III.*a* could not give exact results, as our acquaintance with these stars below magnitude 6·0 is still too imperfect. However, the researches which M. Pechülé undertook, with the aid of the *Uranometria Argentina*, on the distribution of the coloured stars, render it probable that these also are closest together in the neighbourhood of the Milky Way.

I have already said that in all probability the spectra of fixed stars must be subject to variations on account of the diminution in the temperature of stars which must take place sooner or later, and I observed that it is precisely on the supposition of such a diminution that the classes of M. Vogel are based. There are, however, eminent *savants* who have combated the correctness of this opinion, and who have formed ingenious hypotheses to prove the possibility that the sun, and consequently the stars also, may regain the heat which emanates from them. But it would be too much to say that these theories have victoriously withstood criticism, and the spectroscopic examination of the stars has given results fatal to them. Although the spectra of stars may be divided into very distinct classes, according to their characteristics, there are, on the other hand, numerous spectra of all possible grades between any two classes, so that it may be difficult, if not impossible, to decide to what class a star belongs, and that even when it is sufficiently brilliant for all the details of its spectra to be distinctly recognized. Besides, we see that the more the star resembles the first class, the brighter is its violet part, whereas the violet part becomes fainter and fainter or even invisible when the spectrum resembles that of α Orionis (III.*a*). On that account it seems certain that the spectra owe their characteristics to the greater or less degree of incandescence of the stars, so that the temperature of stars of Class III. must be relatively low.

Doubtless these changes do take place in the stellar spectra, although we must suppose that, as regards the spectra of the first two classes, they are almost exclusively secular, and operate so slowly that millions of years may pass before they become apparent.

It is different with stars of Class III. These being probably already much cooler than the others, we may reasonably expect that the changes will take place more rapidly, and perhaps also that from time to time temporary augmentations in activity will take place on their surface, followed by periodic changes in their spectra.

In the course of his observations Secchi arrived at the conclusion that the colours and spectra of these stars were subject to remarkable changes in a very short period. My observations led to the same conclusion, if observations from the years 1866 to 1874 may be trusted without reserve. For, without counting the few and unimportant discrepancies which I discovered between the aspect of several spectra and the descriptions given by earlier observers, I found that there are forty stars which have been comprised in Class III., among which there is scarcely one which now belongs to it, and there are some which ought to have been transported from one sub-class into the other. But, for reasons which I will here explain, such a conclusion would certainly be too hasty.

On the one hand, Secchi's observations date from a time which we may call the infancy of spectrum analysis, and the instruments employed were very imperfect; on the other hand, he was the first to introduce a classification of the stars according to

their spectra. Therefore it is easily understood that Secchi was only able to seize gradually the characteristics of the different types (thus it was not until late that he introduced the fourth type); and again, he once changed the order so that the second and third types changed numbers. On account of this change, some errors may have found their way into his publications. Some even may be explained without having recourse to this supposition. All the spectra which I have excluded from the third class are, according to Secchi, indeterminable, except two, which I consider intermediate between II.*a* and III.*a*, and the two stars R.A. = 9h. 18m., Decl. = − 21° 50′, and R.A. = 18h. 14m. 40s., Decl. = + 25°·2, which Secchi found independently of Schjellerup's catalogue of red stars. It might happen then that with a clear sky faint bands might be perceived,[1] and as to the last we may well suspect that there is some gross error in their positions, judging from what Secchi says as to the manner in which he discovered the first of them.[2] Such a supposition would not be admissible for the star 249 Schj. This star is situated, according to Herschel, amongst a mass of stars, and Secchi says of it, "Stella di 9ª rossa con rigoni nello spettro 4° tipo certamente" ("Memoria Seconda," p. 52). I have often examined the cluster in which this star was situated, but without perceiving it. We may therefore believe that it is variable of long period.

I still have to refer to the stars which ought to have been transferred from one *sub*-class to another. In the spectra of these, variability seems to me quite inadmissible, the two subclasses being, as I shall try to prove soon, co-ordinated, and not successive phases of development which every star must undergo. I suppose that at the commencement of his observations of spectra of the third class, when Secchi met with stars III.*b* not very well marked, he did not think them different from III.*a*, and he did not perceive the difference until after having seen several spectra of this class as pronounced as those of 78 and 152 Schj. On the spectrum of the latter he still says in 1867, "In conclusione è tipo di *a* Ercole ma con zone vere mancanti" ("Catalogo," pp. 14, 15).

However, neither Secchi nor even D'Arrest examined a sufficient number of spectra III.*b* to thoroughly understand their characteristics. Both appear to admit that there are fundamental differences between spectra belonging to it. For instance, Secchi says of the spectrum of star 136 Schj., "E difficile dire se sia proprio del 4° tipo" ("Memoria Seconda," p. 42), and of the stars discovered by Wolf and Rayet with bright lines which are not hydrogen,[3] and dark bands in the spectra, and therefore certainly belonging to Class II.*b*, he says, "Accenneremo qui soltanto che esse appartengono al 4° tipo, ma sono di quelle a zone molto irregolari" ("Sugli spettri prismatici delle stelle fisse," p. 194), and "Ad ogni modo sono di 4° tipo, e le righe paiono del carbonio diretto" (*l.c.* p. 216). D'Arrest speaks as follows of the star 74 Schj., "Irregular spectrum of type IV." (*A.N.* 2016); and of the star 155*b* Schj., "Very remarkable spectrum, &c." (*A.N.* 2009). By collecting all my observations on all the spectra of this class it is seen that not one of them really departs from what may be called the normal spectrum. Doubtless there are in different stars notable differences in the darkness of the flutings, and in the brilliancy of the intervals, but all this does not prevent all the spectra being formed according to one constant type, as happens with Class III.*a*. Besides, Secchi seems to think that the aspect of a spectrum may change completely with the kind of spectroscope used. He says of the spectrum of 132 Schj., "Tipo 4° ben deciso, . . . oculare cilindrico. Coll' oculare piccolo sferico tutto questo era sparito e si credette tipo 3°." When instruments are used which give so vague an appearance to an exceptionally well-defined spectrum, presenting essential characteristics, it is easy to commit serious errors in judging of the spectra examined. Therefore I cannot see that the discrepancies which exist between Secchi's observations and mine are a sign of variations in the stellar spectra, although no doubt it is prudent to occasionally examine the stars concerning which these discrepancies have arisen.

It is quite a different case with the discrepancies that I have found between my observations and those of D'Arrest, who was supplied with excellent instruments, and was a most careful and skilful observer. It is necessary therefore to examine more closely into the cases in which differences exist. There are three, two of which concern the stars 24034 Ll. = Weisse XII.ⁿ 793 and DM. + 60° 1461 = A. Oe. 13681. D'Arrest says that the latter has "a bright well-marked spectrum of type III." (*A.N.* 2044) and the former "a clear, fluted spectrum, the flutings being very distinct although pretty fine, III." (*A.N.* 2009). I found both nearly white, and their spectra II.*a*, or continuous. It is true that I examined the positions of these stars by the help of the two catalogues in which they are, and obtained the same positions, nevertheless one is tempted to believe that D'Arrest made some error in the identification of these stars, especially as he did not observe them several times. This supposition is quite inadmissible, however, for the star DM. + 36° 2772 = Ll. 30500, for here D'Arrest expressly says (*A.N.* 2009), "8·3 mag. with beautiful column-like spectrum. It is one of the stars accompanying the great Hercules nebula." I have calculated the position of this star with the help of the catalogue and of Ll., and besides that I examined all the stars in the neighbourhood of the great cluster in Hercules without finding one of Class III.*a*. The star DM. + 36° 2772 is of orange colour, but its spectrum is continuous, or at most II.*a* very poorly developed. As regards this spectrum I shall not even attempt to explain the difference between what I have seen, and the description given by D'Arrest. A variability of the spectrum seems really probable, and the star is certainly deserving of much attention. Besides this star there are others whose spectra I found very feebly developed, whilst D'Arrest says that they are beautiful or even superb. This also may be regarded as a sign of variability, and a fact which also supports this supposition is that D'Arrest has made his observations under atmospheric conditions generally regarded as similar to those found at Lund with a spectroscope of similar construction to one of ours, and a telescope very little larger than the one which I used. But it is remarkable that whereas I have often found expressions used by D'Arrest to describe spectra stronger than I should have used, the contrary is of very rare occurrence. It is possible, therefore, that the differences are only apparent, and that either D'Arrest's observations were made under exceptionally favourable circumstances, or mine under very unfavourable ones. The latter supposition is scarcely probable however, for when such differences have occurred I repeated the observation several times; and besides, Vogel's observations on the stars between − 2° and + 20° agree almost without exception with mine. It appears, moreover, that very often D'Arrest only made one observation of the same star; and, without depreciating his researches, it seems to me more probable that there are small and rare inexactitudes in the observations, than that such great changes have taken place in the stars themselves in the short period of ten years.

My researches already contradict the hypothesis that important changes in the stellar spectra take place so rapidly. My observations embrace a period of six years, and a much larger number of objects than either D'Arrest or Secchi examined. But there is no spectrum in which my latest observations have differed sensibly from my first ones. It is true that my first observations on the spectrum of R Crateris are in direct opposition to the last, the former making its spectrum III.*b* and the latter III.*a*. But that is in no way a sign of variation in the spectrum. When the bands in the spectrum III.*a* of a faint star are exceedingly broad in the green-blue, it is easy to fall into the error of regarding it as III.*b*. At the time of M. Vogel's first observation he also believed that the spectra of stars DM. + 14° 2525 and DM. + 17° 3940 were III.*b*, and it is true that these two spectra, especially the last, are strikingly like the spectra III.*b* in spectroscopes of small dispersion.

It was in order to escape such errors that I determined in the spectra of most of the faint stars of Class III.*b* the approximate wave-lengths of their principal flutings; the wave-length of band 6, and also that of band 10, being a sure mark that the spectra belonged to this section of Class III. This deceptive appearance generally disappears when the star is examined with spectroscopes of considerable dispersion. I am therefore at present of opinion that, excluding the new stars and perhaps η Argûs, which seems to belong to the same category, we have no reason to believe that great and rapid changes take place in the stellar spectra, although it must be confessed that the observations of certain stars, especially DM. + 36° 2772, are such as to render such changes very probable.

(*To be continued.*)

[1] M. Vogel has as a matter of fact seen feeble bands in the spectrum of one of them − 60 Schj., while in the case of ten stars his observations confirm my own; in the spectrum of another star M. Pechülé has not seen any bands.

[2] "Trovata cercando 124 Schj." The position of this star differs by 27m. and 40′ from that of the star in question.

[3] In his observations at Vienna with the great refractor, M. Vogel was able to see the lines of hydrogen either C or F in the spectra of all three stars; they were, however, feeble in comparison with the other bright lines.

THE ART OF COMPUTATION FOR THE PURPOSES OF SCIENCE.

I.

THE art of computation as distinguished from the science of arithmetic it so generally neglected in our ordinary courses of education, that most men and almost all women feel the greatest difficulty and repugnance in dealing with figures. The causes of and remedies for this deficiency are discussed at some length in a paper "On teaching Arithmetic" (*Journal of Education*, May 1885), and the following remarks refer specially to the requirements of students of science.

I must apologize for the use in proving my case of some names of high and well-deserved repute. Instances are given, as far as possible, which have been publicly acknowledged or corrected, with the full admission that this paper is itself a house of glass, and that any stone may impinge even upon Newton, since, as Lord Lytton tells us, "that great master of calculations the most abstruse could not accurately cast up a sum in addition. Nothing brought him to an end of his majestic tether like dot and carry one."

In 1867 Mr. Stone pointed out two numerical errors in Leverrier's determination of the solar parallax.

Prof. J. D. Van der Plats writes (*Chemical News*, July 30, 1886):—"The verification to which I have submitted the calculations of M. Stas seems superfluous seeing that it deals with the experiments of a *savant* who has never had an equal in exactitude. It may perhaps astonish some as much as it did me to find that the original memoirs contain numerous arithmetical mistakes, as well as typographical errors, of which some are considerable."

Mr. J. Y. Buchanan writes (NATURE, vol. xxxv. p. 76):—"There is a statement in NATURE for November 11 that the weight of the column of water between 20 fathoms and 70 fathoms from the surface under the westerly equatorial current is only 88 per cent. of the weight of the same column under the easterly counter equatorial current. I regret that a serious arithmetical error occurs in the calculation on which this statement was founded. There is no such considerable difference of weight in the two columns of water." Suppose at the equator the Guinea current flows from west to east at the rate of 40 knots in twenty-four hours, and that the equatorial current flows at 30 knots in twenty-four hours in the opposite direction. The opposite directions of the two currents cause an additive and subtractive difference in the tangential velocity of the particles of water due to the rotation of the earth, and therefore an apparent difference in the acceleration due to gravity of about 1/46000, or a pressure equal to that of an additional 1/13 of an inch of water on the column of 50 fathoms.

On page 84 of the *first* edition (the second has been corrected) of Prof. Huxley's admirable "Physiography," we read:—"The weight of air on a square mile is about 590,129,971,200 lbs., and the carbonic acid which it contains weighs not less than 3,081,870,106 lbs., or about 1,375,834 tons. The weight of the carbon in this carbonic acid is 371,475 tons."

This short statement contains excellent examples of many of the common arithmetical slips and errors.

The first number is ten times too great, and not quite accurately calculated from the data $(5280)^2 \times 144 \times 14{\cdot}73 = 59{,}133{,}431{,}808$. Multiplying this by $\frac{\cdot 05321}{100}$, the proportion by mass of carbonic acid in the air, we obtain 31,464,899; here, besides a slip, the number is again multiplied by ten. The pounds are reduced to tons correctly, but there is a slip in the reduction to carbon, since

$$\frac{1{,}375{,}834 \times 3}{11} = 375{,}227.$$

Many more instances might easily be brought forward, but the above will suffice to prove that even the highest attainments in science are too often accompanied by inaccuracy in arithmetic. The causes of this defect have been frequently discussed, but, with the exception of De Morgan and his pupils, little advance in the methods of teaching arithmetic seems to have been made since the days of Recorde and Cocker.

The teachers of arithmetic in our public and higher-grade schools are usually good mathematicians who, in their own school-days, have been hurried through the hated subject to higher work, and have had no subsequent experience in the practical computation required in the laboratory, workshop, or counting-house. When compelled to work out a sum for themselves, the theory is supplied by their knowledge of algebra, and the practical work by a table of logarithms. When brought face to face with the fact that their pupils dislike and are very weak in arithmetic, they fall back upon the stock argument that they teach arithmetic as a training for the mind, and not as a useful art. In too many cases it is to be feared that they are not teaching arithmetic at all.

The great majority of the text-books in common use seem to be defective from the point of view of a student of science in at least three points.

More than half the rules and examples are devoted to money, and arithmetic is treated as though it applied only to pounds, shillings, and pence.

Secondly, few give any suggestion as to the use of tables in lightening arithmetical work, and a boy leaves school disgusted with long rows of figures in which he sees no utility, and without any idea to how large an extent the work could be lightened.

Lastly, the various methods of dealing with approximate quantities are omitted, and a painstaking boy calculates vast collections of figures of which only two or three have any meaning.

Thus Prof. Huxley gives the tenth figure, 6, in the expression for the amount of carbonic acid on a square mile, ignoring the facts that while the percentage of carbonic acid varies in the first figure, its density is not known to the fourth, and the pressure of the air varies in the second.

It is convenient to bear in mind the following simple rules, due, I believe, to De Morgan. If two numbers, a and b, each true to the first decimal place, are multiplied together, the result is true to $\frac{a + b}{20}$ only; a second true decimal in *each* number makes the result ten times more correct, and so on. In dividing a/b where each is true to the first place, the result is true to $\frac{a + b}{b^2 \times 20}$ and so on. Any attempt at greater accuracy in calculation than is indicated by these results should be avoided, since it only precludes the use of cheap and handy tables, tires the calculator making him more liable to error in the important figures, and tends to give quite a false idea of the accuracy of the experiments on which the calculations are based; unless, indeed, we take seriously the answer of Dulong when asked why he always gave his results to eight figures, "I don't see why I should erase the last decimals, for, if the first figures are wrong, possibly the last are correct."

The natural tendency of the human mind, even if controlled by mathematical and scientific training, is to exalt the accuracy of one's own experiments. This is well shown by Prof. Ramsay and Dr. Young in discussing the vapour-tension of liquid benzene (Proc. Phys. Soc., January 1887):—

"A curve was drawn to represent these (experimental) relations, and from it three points were chosen, 0° C. 26·54 mm., 40° C. 180·2 mm., and 80° C. 755 mm. The constants for the formula $\log p = a + b\alpha^t$ are $a = 4{\cdot}72452$, $\log b(-) = 0{\cdot}5185950$, $\log \alpha = \bar{1}{\cdot}996847125$." *Nine* places of decimals are given with apparent confidence, when (1) only three of the whole number of experiments were made even in duplicate; (2) the last pressure, 755, was obtained not by experiment at all, but by extrapolation from a freehand curve, the highest experiment being 79°·6 and 743·1 mm.; (3) a difference of $\frac{1}{8}$° at low temperatures produced no change in pressure which was appreciable by the apparatus used. With the above-mentioned constants the author's calculate for 60° C. 388·51 mm. Using their data and a table of four-figure logarithms, I find $a = 4{\cdot}7239$, $b = -3{\cdot}3$, $\log \alpha = \bar{1}{\cdot}99684$, which gives for 60° C. 390 mm. Regnault gives 390·1 mm.

Under suitable conditions the observation of one quantity can be made with great exactness. It is possible that Sir George Airy estimated 1/100 of a second in a day, or 1/8,640,000; that a balance can be made to estimate 1/1,000,000 of the load, though those of Stas were only accurate to 1/825,000; and that Sir J. Whitworth measured the 1/1,000,000 of an inch. These cases, however, are exceptional, and give quite a wrong idea of the accuracy attainable in ordinary observations and experiments, when several operations, each liable to error, have to

be performed, and various corrections introduced by calculation from extraneous data.

The more closely we examine work of the highest accuracy the more convinced we become of the truth of the statement of Thomson and Tait (p. 333): "Few measurements of any kind are correct to more than *six* significant figures." Thus the number of inches in a metre was found by Capt. Kater in 1821 to be 39·37079, and by General Clarke in 1866 to be 39·37043; this fundamental datum therefore is affected by a doubt of nearly 1/100,000, which of course affects all results dependent on it. In 1856 Miller found that a cubic foot of water at 62° F. weighs 62·321 lbs. From Kater's result a cubic foot contains 28·3153 cubic decimetres, and the mean of a large number of experiments, especially those of Lefevre Gineau, and Kupffer, make the cubic decimetre of water at 4° C. to weigh a kilo = 2·20462125 lbs. according to Miller. Hence a cubic foot of water at 4° C. weighs 62·4255 lbs.; and taking the expansion from Förster (1870), which is nearly identical with that used by Miller, the weight at 16°·67 C. becomes 62·355 lbs.; or about 1/2000 heavier than Miller's determination. But these are the results obtained by picked men under all conditions to insure the greatest accuracy. Results which agree to two or three in the fourth figure show an exceptionally good chemist, while a physicist must be careful indeed to obtain numbers concordant to the fifth figure.

For practical purposes, then, calculations in science may be divided into two classes. The great majority of experiments in physics, chemistry, biology, geodesy, mensuration, navigation, and crystallography are not to be trusted beyond the fourth or fifth figure. Hence a similar accuracy in calculation is all which is required. Some few experiments in each branch—such as the work of Kater, Regnault, Stas, some observations in astronomy, and a few reductions in sociology—may require six or eight figures to be accurately dealt with.

In pure mathematics, of course, numerical results may be pushed to any extent compatible with even the partial sanity of the calculator.

The following suggestions are intended to assist such of my readers as are not mathematicians in working sums of each class by the aid of tables.

Mechanical aids, such as slide rules, arithmometers, and the like, are purposely omitted, since they would require a paper to themselves. The objection to the larger and more powerful is that they are expensive and complicated; that they require a good deal of practice on the part of the operator to give accurate results; and that they are not readily adapted to work shorter sums than they are intended for. On the other hand, a slide rule is an almost indispensable servant when once one has learnt the use of it for dealing rapidly with comparatively small numbers; for large numbers it becomes very cumbrous.

The two cardinal points in approximate working are the short methods of multiplying and dividing decimals suggested by Oughtred in 1631, and strengthening the last figure retained when the first omitted is above 4. For greater accuracy it is well to mark all strengthened figures, and to allow for an excess or defect of them; as a further security one figure beyond what is required may be calculated.

Tables of the multiples from 1 to 9 of numbers which frequently occur are of great assistance especially when the calculator is tired. They are easily made by repeated additions or by the use of the convenient "automatic multiplier" of Mr. Sawyer, which is merely a modern adaptation of Napier's bones.

The due use of complements and reciprocals saves a good deal of time in subtraction and division.

Tables for general use and special purposes are very numerous. For our present purpose they fall naturally into three classes. Five kinds of tables should be in the hands of all calculators:—

1. Multiplication tables such as those of Crelle, by the aid of which three figures may be dealt with at once with greater certainty than is usually the case with one. Tables of primes and factors are not much required for scientific purposes.

2. Reciprocals, which reduce division to the short multiplication of decimals, render the addition of fractions easy, and assist chemists in percentage compositions.

3. Squares, cubes, square roots, cube roots. For most purposes in chemistry and physics a small table up to 100 is sufficient, especially when aided by the following convenient method of approximating to a cube root. If a^3 be the nearest exact cube to the given number N, $N = (a \pm b)^3 = a^3 \pm 3a^2b + 3ab^2 \pm b^3$, or if b be small, $\pm b = \frac{N - a^3}{3a^2}$. Thus to find $\sqrt[3]{28}$, $a = 3$, $b = \frac{28 - 27}{27} = \cdot 037$, $\therefore \sqrt[3]{28} = 3\cdot 037$ instead of $3\cdot 0366$.

De Morgan's edition of Barlow is very convenient, and suffices for all ordinary purposes.

4. Common logarithms to four and five figures. Four-figure tables are perhaps most convenient on one face of a card. Hoüel's reprint of Lalande, with some changes and many valuable additions, is cheap and most convenient in form; it quite suffices for all common work.

For the reasons already mentioned seven-figure tables are unnecessarily cumbrous and expensive for ordinary work. They should never be put into the hands of beginners, as is now the usual practice. Experience shows that boys learn the method of using and appreciate the value of logarithms far more readily than is generally supposed.

5. Gauss's sum and difference logarithms are valuable in dealing with certain trigonometrical formulæ and with questions of expansion.

In the second class may be placed those general tables which are less commonly required, such as:—

1. Powers of 2 and other numbers. Cohn tells us that some varieties of Bacterium multiply by fission every hour, hence by the end of a day one individual would increase to $2^{24} = 16,777,216$. We may therefore cease to wonder at the rapid spread of some forms of infection.

2. Factorials are required in solving permutations and combinations, and therefore in all questions relating to probabilities. Hatchett recommended that a systematic examination of all possible alloys of all the metals should be undertaken. He forgot to remind anyone who attempted to follow his advice that if only one proportion of each of thirty common metals were considered, the number of binary alloys would be 435, of ternary 4060, and of quaternary 27,405. If four multiples of the atomic weight of each of the thirty metals be taken, the binary compounds are 5655, ternary 247,660, quaternary 1,013,985.

3. The sums of arithmetical series are so readily obtained that they are rarely tabulated.

4. Geometrical series are required in certain social questions, such as the increase of population and the output of coal. Tables of the sums of these series when the ratio is nearly one are common, and of considerable use in some scientific problems.

5. For some purposes it is convenient to express numbers in a scale different from the common decimal one.

Thus (Clerk Maxwell, "Elementary Electricity," p. 180) a series of resistance coils are best arranged according to the powers of 2, since the smallest number of separate coils is required, and they are most readily tested. The same is true for a set of weights. Thus to express from 1 to 100 gm. 9 weights are ordinarily provided; 9 weights in the scale of 2 will express up to 511 gm., while 7 weights suffice for 100 gm., since 100 in the scale of 2 is expressed by 1100100.

6. The curious theory of trees due to Profs. Cayley and Sylvester (B. A. Report, 1875) seems to promise the possibility of computing the number of possible compounds formed by elements of given valency. Thus x atoms of tetravalent carbon will combine with monad hydrogen to form N compounds.

x	N	x	N	x	N.
1	1	6	18	11	1346
2	1	7	42	12	3326
3	2	8	96	13	8329
4	4	9	229		
5	9	10	549		

If of the first thirteen paraffin hydrocarbons alone there are 13,952 possible forms each with its own series of derivatives, there seems little chance of chemists having nothing to do for some time to come.

7. Natural logarithms are required by some formulæ, and are at times more convenient than common logarithms.

According to Haughton ("Animal Mechanics," p. 282), the study of the action of certain muscles requires the use of natural logarithms.

The ratio of the mean absolute pressure P to the initial absolute pressure p in a steam-cylinder at the given rate of expansion r is expressed by $\frac{P}{p} = \frac{1 + \text{nat. log } r}{r}$.

Weldon supposed (B. A. Report, 1881), that some power of

the atomic weight (X) of each of the first fourteen elements in Mendelejeff's classification is a simple multiple of the same power of the atomic weight of lithium. Or $X^x = m7^x$

$$l.\ X = 1{\cdot}9459 + \frac{l.\ m.}{x}$$

It is easy to see that since x may be any whole number, and m any small whole number, X may have any value whatever within the limits of errors of experiment; or the relation is fanciful rather than real.

S. Values of the definite integral $\frac{2}{\sqrt{\pi}}\int_0^x e^{-x^2}dx$ representing the probability curve, upon which the whole science of the adjustment and comparison of quantitative experiments is based.

Tables of the third class, which offer special facilities to those engaged in any one kind of work, are very numerous.

The physicist has Rankine's "Rules and Tables," Everett's "Units and Physical Constants," Hospitallier's "Formulaire de l'Electricien," and many others.

The chemist has Biedermann's "Kemiker Kalendar," the "Agenda du Chemiste," and various tables for analysis, such as those at the end of Fresenius.

The needs of both physicists and chemists are more or less supplied by Landolt and Bornstein's "Tabellen," the "Annuaire du Bureau des Longitudes," and my own more portable "Numerical Tables and Constants in Elementary Science."

I know of no such numerical compendium dealing with biology, but have often felt the want of one.

To sum up briefly the points which have been so far touched upon. The great majority of numerical problems which really occur in scientific work only require four figures to be accurately dealt with; hence a little ingenuity will generally bring them within the range of small tables. They should be worked out neatly, and as briefly as is consistent with the requisite accuracy; all useless figures should be rigorously excluded as misleading. Some few problems require the use of more powerful tables. Six-figure tables, such as those in Weale's series, and Collins's Logarithms for practical men, are little used, and inconvenient in practice. Seven-figure tables, such as Callet, Hutton, Babbage, Chambers, Schrön, Bremiker, Bruhns, Sang, so far as numbers go are nearly equally good; they differ chiefly in the trigonometrical ratios, which lie outside our present subject, and also considerably in price. SYDNEY LUPTON.

(*To be continued.*)

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, December 20, 1887.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of November 1887.—Mr. Sclater read a letter from Dr. H. Burmeister containing a description of a supposed new Humming-bird from Tucuman. Mr. Sclater proposed to call this species, of which the type was in the National Museum of Buenos Ayres, *Chætocercus burmeisteri.*—The Secretary exhibited, on behalf of Major Yerbury, a pair of horns of the Oorial (*Ovis cycloceros*), which formerly belonged to the Royal Artillery Mess at Fort Attock, and were stated to have been originally obtained in the Chitta Pahar Range, a few miles south of Attock. These horns were apparently of the form lately described by Mr. A. O. Hume as *Ovis blanfordi.*—An extract was read from a letter received from Mr. H. M. Phipson, of the Bombay Natural History Society, offering some living Snakes for the Society's collection.—Mr. F. E. Beddard read a paper on Hooker's Sea-lion, *Otaria* (*Arctocephalus*) *hookeri*, based upon the specimens of this species recently received by the Society, one of which had lately died. The author called attention to the external features, visceral anatomy, and osteology of this Sea-lion, in comparison with the corresponding characters of other species of the group.—Mr. G. A. Boulenger read the description of a new genus of Lizards of the family Teiidæ, founded on a specimen presented to the British Museum by Mr. H. N. Ridley, who had obtained it in the forest of Iguarasse, Pernambuco. The author proposed to name this Lizard *Stenolepis ridleyi.*—A communication from the Rev. H. S. Gorham, entitled a "Revision of the Japanese species of *Endomychidæ*," was read. In this paper three new genera and thirteen new species were characterized and described. Additional observations were made upon the species previously known to inhabit Japan. The new species were based on specimens obtained by Mr. George Lewis during his last journey to the islands in 1880-81.—Mr. G. A. Boulenger gave an account of the fishes obtained by Surgeon-Major A. S. G. Jayakar at Muscat, east coast of Arabia, which had been presented by him to the British Museum. The collection contained specimens of 172 species, many of which were unrepresented in the national collection, and fifteen of which were apparently new to science.—Mr. H. Druce read a paper containing descriptions of some new species of Lepidoptera Heterocera, from Tropical Africa.

EDINBURGH.

Royal Society, December 19, 1887.—Sir Douglas Maclagan, Vice-President, in the chair.—Mr. John Murray communicated a paper on the height and volume of the dry land, and the depth and volume of the ocean. The mean height of the land above sea-level is 2250 feet. Only 2 per cent. of the ocean is included inside a depth of 500 fathoms. Seventy-seven per cent. lies between depths of 500 and 3000 fathoms. The mean depth of the ocean is 12,480 feet. If all the land were utilized to fill up hollows on the earth's surface, the sea would cover it to a uniform depth of 2 miles.—Sir W. Turner read a paper on the pineal gland in the walrus. The gland is excessively developed backwards, being visible from above without any dissection of the brain. The author contrasted it with the same gland in the lizard which is prolonged forwards and ends in the pineal eye. The cerebral lobes in the lizard are small, while those of all mammals are large. He suggested that the development of the lobes may have carried the gland backwards, and caused atrophy of the prolongation ending in the pineal eye. The atrophy, on the other hand, might have been caused by ossification extending over the aperture where the eye is situated.—Dr. Byron Bramwell described a method which he and Dr. Milne Murray had used successfully to record the exact time-relations of cardiac sounds and murmurs.—Prof. Crum Brown submitted a paper by Prof. Letts on the benzyl phosphines.—Dr. H. R. Mill read a criticism by Dr. Guppy on the theory of subsidence as explaining the origin of coral reefs.—Prof. Tait discussed the compressibility of water and of different solutions of common salt. Perkins proved sixty years ago that water becomes less compressible as the pressure is raised. At high pressures then it may be roughly assimilated to an extremely compressed gas. If the gas be regarded as consisting of hard spheres, the curve representing the relation between pressure and volume is approximately hyperbolic. The first asymptote of the hyperbola indicates what must be added to the external pressure to give the whole pressure to which the liquid is subject. The second indicates the ultimate volume to which it could be reduced by an infinite pressure. Applying this to the experimental results given to the Society in July last, the author showed that the pressure in water under ordinary circumstances is somewhere about thirty-two tons' weight per square inch; and the ultimate loss of volume under infinite pressure is about 25 per cent.

PARIS.

Academy of Sciences, December 26, 1887.—M. Janssen, President, in the chair.—Annual address, by M. Janssen. After brief reference to the losses sustained by the Academy during the year by the deaths of the illustrious *savants* MM. Paul Bert, Gosselin, Boussingault, and Vulpian, the President passed on to speak of recent scientific progress in France. Special mention was made of the magnificent Observatory just completed at Nice, for which the munificent founder, M. Bischoffsheim, receives the Arago Medal, now for the first time awarded. Allusion was also made to the isolation of fluorine effected by M. Moissan, and to the development of stellar photography, declared to be an "invention d'origine toute française." Nevertheless reference is made to the preliminary work of the English and American labourers in this field, Rutherfurd, Warren de la Rue, Bond, and Gould.—The Presidential allocution was followed by the announcement of the prizes for the year 1887, by the Secretary, M. J. Bertrand, who also read a paper on the life and work of the distinguished engineer, Stanislas Charles H. Laurent Dupuy de Lome.

Subjoined are the names of the successful competitors for the annual prizes. *Geometry:* Prix Francœur, M. Emile Barbier; Prix Poncelet, M. Appell. *Mechanics:* Extraordinary Prize of 6000 francs, divided between MM. Héraud, Dubois, Rouvier, and Moisson; Prix Montyon, M. Paul Vieille; Prix Plumey, M. Guyou. *Astronomy:* Prix Lalande, M. Dunér; Prix Valz, M. Perigaud; Prix Janssen, the late M. Kirchhoff. *Physics:* Grand Prize for the Mathematical Sciences, M. Willotte; Prix La Caze, MM. Paul and Prosper Henry. *Statistics:* Prix Montyon, MM. Victor Turquan, de Saint-Julien, and G. Bienaymé. *Chemistry:* Prix Jecker, MM. Arnaud and A. Haller; Prix La Caze, M. Moissan. *Geology:* Prix Delesse, M. Gorceix. *Botany:* Prix Barbier, MM. Edouard Heckel and M. Schlagdenhauffen; Prix Desmazières, MM. Ardissone and Dangeard; Prix Montagne, M. Boudier. *Anatomy and Zoology:* Grand Prize for the Physical Sciences, M. Raphael Dubois. *Medicine and Surgery:* Prix Montyon, Drs. Henri Leloir and E. Motais, and MM. Nocard and Mollereau; Prix Bréant, MM. Galtier, Chantemesse, and Widal; Prix Godard, M. Azarie Brodeur; Prix Chaussier, Dr. Jaccoud; Prix Serres, M. Alexandre Kowalevsky; Prix Lallemand, MM. Pitres, Vaillard, and Van Lair. *Physiology:* Prix Montyon, M. Ch. E. Quinquaud; Prix L. La Caze, Dr. Ch. Rouget. *Physical Geography:* Prix Gay, MM. Alfred Angot and Wilhelm Zeuker. *General Prizes:* the Arago Medal, M. Raphael Louis Bischoffsheim; Prix Montyon (Unhealthy Industries), Dr. Edouard Heckel; Prix Trémont, M. Jules Morin; Prix Gegner, M. Valson; Prix Petit d'Ormoy (Mathematical Sciences), the late M. Laguerre; Prix Petit d'Ormoy (Natural Sciences), M. Balbiani; Prix Laplace, M. Jules E. R. de Billy.—Honourable mention was made of the two English physiologists, Drs. Augustus D. Waller and E. Waymouth-Reid, for their memoir on the excised heart of mammals, published in the *Comptes rendus* for May 31, 1887. This study contains a number of new and highly interesting facts regarding the electric phenomena of the heart, the duration of the regular action of its four parts after excision, and the slowness acquired under certain circumstances by the wave of cardiac contraction.—Amongst the more important prizes offered for competition under the usual conditions during the years 1888 and 1889 are the following:—*Geometry:* Grand Prize for the Mathematical Sciences, to complete the theory of algebraic functions of two independent variables; Prix Bordin, to complete in some important particular the theory of the movement of a solid body. *Mechanics:* Prix Fourneyron, theoretic and practical essay on the progress of aërial navigation since 1880. *Astronomy:* Prix Damoiseau, to complete the theory of the irregularities occurring at long intervals in the motion of the moon caused by the planets. *Physics:* Grand Prize for the Mathematical Sciences, to complete in some important particular the theory of the application of electricity to the transmission of labour. *Agriculture:* Prix Vaillant for the best work on the diseases of cereals. *Anatomy and Zoology:* Grand Prize for the Physical Sciences, a complete study of the embryology and evolution of any animal, at the option of the candidate; Prix Bordin, comparative study of the auditory apparatus in warm-blooded Vertebrates, mammals and birds. *Physical Geography:* Prix Gay, to prepare monthly charts of the surface currents in the Atlantic, with a survey of the movement of drift ice in the waters about the Arctic regions; Prix Gay, to determine by a comparative study of their respective faunas and floras the relations formerly existing between the Polynesian Islands and the neighbouring lands.

Astronomical Society, November 9, 1887.—M. Flammarion, President, in the chair.—The President read a paper on some observations on the relative colours of stars, which he had made in 1875 by means of a specially constructed sextant in which the images of two stars wide apart could be brought into the same field.—M. Detaille read a paper on the photography of the solar spectrum with a direct-vision spectroscope, and stated that this subject was quite within the reach of amateurs, on a small scale of course, and presented many interesting points. He showed some negatives and positives obtained with a small instrument.

December 14.—M. Flammarion, President, in the chair.—The meeting was opened by the distribution of the calendar reform prizes, amounting, in medals and money, to the value of 5000 francs (an anonymous gift):—1st prize, 1500 francs, M. Gaston Armelin, of Paris; 2nd prize, 1200 francs, M. Hanin, of Auxerre; 3rd prize, 1000 francs, M. Francis de Roucy, of Compiègne; 4th prize, 800 francs, M. Barnout, of Paris; 5th prize, 250 francs, M. Remy Thouvenin, of Nancy; 6th prize, 250 francs, M. Blot, of Clermont (Oise).—M. Flammarion read a paper on some probable common proper movements of certain stars. In looking over the catalogue of the Paris Observatory, he had observed that several stars in Taurus—namely, Lalande 8178, 8209, 8237, 8256, 8297, 8404—had no motion in declination, and had all about the same proper motion in R.A. The same remarks apply to θ^1 and θ^2 Tauri. The two stars γ Leporis and Lalande 10931 seem also to be connected.—Colonel Laussedat, Director of the Conservatoire des Arts et Métiers, exhibited a curious binocular glass, constructed for Louis XIV. by Father Seraphin in 1681. This huge instrument comprises three rectangular bows which slide into each other. The length of the whole affair is no less than 3 metres 10 centimetres.—M. Neuville, in a letter, notices that the minimum of Algol seems longer than 6 minutes as given by several authors. He adopts 18 minutes, and gives a probable size of Algol's dark companion.—MM. Paul Henry and Detaille remark that Webb gives 18 minutes as the duration of Algol's minimum.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Birds of Wiltshire: Rev. A. C. Smith (Porter).—Arithmetic Papers: S. J. D. Shaw (Deighton, Bell, and Co.).—Major Lawrence, F.L.S., 3 vols.: Hon. E. Lawless (Murray).—Catalogue of the Fossil Mammalia in the British Museum; Natural History, Part v.: R. Lydekker (London).—Prodromus of the Zoology of Victoria, Decades 1–14: F. McCoy (Melbourne).—The Theory and Use of a Physical Balance: J. Walker (Clarendon Press).—Journal of Anatomy and Physiology, January (Williams and Norgate).

THURSDAY, JANUARY 12, 1888.

PHYSICAL CHEMISTRY.

Lehrbuch der Allgemeinen Chemie. Von Dr. Wilh. Ostwald. In Zwei Bänden. (Leipzig: W. Engelmann, 1885-87.)

THE larger text-books of chemistry have generally been devoted to describing and roughly classifying the facts which form the foundation of the science. These facts are so numerous, varied, and important, that when one has spent years in arranging, cataloguing, and reciting them, his chemical vision has generally acquired a fixed downward direction, and he is almost unable to lift his eyes from the foundation-stones to look on the buildings which other workers have been raising.

But, whether such a one will look at the building or not, the building is surely rising. The walls already are massive; there are adornments of conceits, perhaps sometimes too quaint; windows there are in plenty to admit light and air: the house will never be completed, because nature is inexhaustible, but even now there is promise of a goodly building. Nor shall the House Beautiful want fit interpreters, among whom an honourable place will be held by the Professor of Physical Chemistry at Leipzig.

It has generally been admitted that chemistry is a branch of physical science. Individual chemists by their researches have shown that the relation of chemistry to physics is that of the less to the greater; but most of the attempts to set forth this relationship in its entirety have failed. To treat chemistry as a branch of physics requires one who is almost as much a physicist as a chemist, but one whose physical training has waited on his chemical judgment. Some books on physical chemistry have been books on descriptive chemistry, with scraps of physical facts thrown in; others have been books on physics to which the use of chemical illustrations has given an ill-defined but not unpleasing chemical tone. Only of late years has it become possible to set forth the connections between the parent science and the greatest of her children in a fairly satisfactory manner; and this possibility has come through the recent advances made in the study of these connections.

It was therefore fitting that one of the men whose work forms no small part of all of first-class importance that has been done in recent years in the sphere of physical chemistry should be the man to write the first good text-book on general chemistry considered as a branch of physics. Ostwald prefers to call his work "Lehrbuch der Allgemeinen," rather than "physikalischen," "Chemie." The title very happily expresses the scope and character of the book; but the treatment of chemical principles in a general manner is made possible in this treatise by regarding chemistry as a special branch of physics. The book is intended for fairly advanced students who have already a tolerable knowledge both of descriptive chemistry and of physical principles. Some of the higher forms of mathematical analysis are freely employed. The form in which the author has chosen to present his treatise is the historical-critical; he justly remarks that the historical coincides with the logical development of many chemical ideas.

As the object of the work is to enable the student to gain a firm hold of the principles of chemistry, and more especially to teach him that very many of these principles have been reached by the application of physical methods to chemical phenomena, much care is taken to distinguish generalized statements of facts from hypotheses, to indicate the need of using hypotheses, to trace the merging of several hypotheses into one general theory, and to avoid mere speculation.

The first volume is devoted to stochiometry. The laws of chemical combination, which form the basis of the whole science, are laid down in a singularly clear and succinct manner; the atomic theory of Dalton is sketched; the chemical methods by which combining weights are determined are classified, and this is followed by a short critical exposition of the results obtained for each element. The second, third, and fourth books of the first volume are devoted to accounts of the properties of gaseous, liquid, and solid bodies, respectively. The relations between the volume, temperature, and pressure of gases, are considered; this leads to a statement of the law of Gay-Lussac, and a consideration of Avogadro's hypothesis; then follows an account of the kinetic theory of gases, the specific heats, and the optical properties of gases. The book on liquid bodies is devoted to a consideration of (1) the general properties of liquids; (2) the relations between the liquid and gaseous states; (3) the volume-relations of liquids; (4) solution; (5) optical properties of liquids; (6) capillarity, diffusion, and osmosis; (7) electrical conductivities and electrolysis of liquids; (8) specific heats of liquids. The book on the stochiometry of solid bodies includes the consideration of crystallography, especially in its chemical bearings, the optical and electrical properties of solids, &c. The first volume concludes with a sketch of the relations between atomic weights and chemical properties, a general account of the molecular theory as applied in chemistry, and a short but very suggestive chapter on theories of chemical composition and constitution.

The second volume deals with the vast and widely ramifying subject of chemical affinity. The first part, on chemical energy, comprises what is really a comprehensive treatise on thermo-chemistry, and also full critical accounts of photo-chemistry and electro-chemistry. The second part, dealing more distinctly with chemical affinity, begins with an historical sketch; this is followed by about 150 pages on chemical dynamics; and the whole concludes with an account of the various methods whereby measurements of the relative affinities of various bodies, especially acids and bases, have been obtained; the last chapter deals with the relations between the nature, composition, and constitution of bodies, and the values of their affinity-constants.

Ostwald has undertaken and brought to a conclusion a task of great difficulty. His book has removed the sting from the taunt so often cast at the chemist that chemistry is the pursuit of the mere fact-finder and formula-monger. If Ostwald's "Lehrbuch" had only made evident the fact that chemistry is one of the exact sciences it would have done much; but it has done more than this; it is a repository of the general and abstract truths of the

science arranged in logical sequence; it is a guide to the student and the investigator (for in chemistry these two are one); and it is full of suggestions alike to the physicist and the chemist.

That part of the second volume which deals with the recent developments of the study of chemical affinity will probably be found by many to be the most interesting portion of the book. Everyone knows how unsatisfactory is the treatment of this subject in the standard text-books. Who has not been perplexed as he attempted to gain clear conceptions about affinity? Affinity is one of those terms that escape one as soon as one tries to grasp it: it is protean, and each form which it assumes scarcely lasts long enough for one to distinguish it from the others.

The work of Guldberg and Waage, published twenty years ago, did not bring forth much fruit for some time; perhaps because these naturalists were obliged to go back sixty years to find in the writings of Berthollet the germs of a really exact treatment of the subject of affinity. But within recent years great advances have been made—and made, speaking broadly, on the lines laid down by the Norwegian professors. No one has had more part in these advances than Ostwald; to him we are indebted for several new experimental methods for finding values for the affinity-constants of acids and bases—indeed the proof of the existence of a measurable affinity-constant for each acid and base is, for the most part, due to him. It is one thing to know that memoirs are to be found in the journals wherein the subject of affinity is gradually advanced stage by stage, but it is quite another thing to have a clear, logically arranged, and condensed account of these memoirs in a text-book. It is one thing to be told that the modern development of affinity is the outcome of the views which Berthollet published, in 1803, in the *Essai de Statique Chimique;* it is quite another thing to have this historical and logical development set before one in detail in a masterly manner.

The subject of affinity is largely involved in the wider conception of chemical equilibrium. Ostwald gives a short account of the attempts which have been made to formulate the laws of chemical equilibrium. He then narrows the meaning of affinity, at least as applied to acids and bases; by doing this it becomes possible to extricate the notion of affinity from the mass of more or less connected facts which had threatened to swamp it, and to give it a quantitative meaning.

The affinity-constants of acids and bases are numbers which tell how much of a definite chemical action those bodies are capable of performing under definite conditions. The formulæ of the same acids and bases exhibit the composition of definite masses of these compounds, which masses are in many respects chemically comparable. The goal of chemistry has always been to trace definite connections between the composition of bodies and their chemical properties; but of all the chemical properties of a body the most important is its affinity-constant, inasmuch as we are apparently justified in saying that this value quantitatively conditions all the chemical reactions in which the body takes part: hence the importance of accurately tracing the connections between the changes of compositions of bodies, as represented by their formulæ, and the variations in the values of the affinity-constants of these bodies, must be very great. The data are as yet insufficient to allow of more than a beginning in this direction: such a beginning is made in the last chapter of Ostwald's book.

To everyone who hopes to make chemistry the business of his life I would say—get Ostwald's "Lehrbuch," read it, study it, become acquainted with it, use it; for by doing this you must become more fitted for doing your work as a chemist. M. M. PATTISON MUIR.

BRITISH AND IRISH SALMONIDÆ.

British and Irish Salmonidæ. By Francis Day. 12 Plates. (London and Edinburgh: Williams and Norgate, 1887.)

IN this work Mr. Day expounds in greater detail the views he made known in his "British and Irish Fishes," concerning the characters and affinities of the several British forms belonging to the genus Salmo. He also includes in the volume the consideration of many other important problems connected with the natural history of British Salmonoids. On p. 9 he gives a synopsis of the British genera of the family, viz. Salmo, Thymallus, Coregonus, Osmerus, and Argentina, and then proceeds to consider Genus 1, Salmo, while at p. 278, is the heading Genus 2, Thymallus, Cuvier. For the designation of species and varieties English names are generally used, but with each is given a copious list of the Latin Linnean synonyms, and references to the works where they occur. The species considered are as follows: the Salmon, Trout, British Char, American Char or *Salmo fontinalis*, and the Grayling. Thus Coregonus, Osmerus, and Argentina are left outside the scope of the book, notwithstanding its comprehensive title.

Very elaborate descriptions, including enumerations and dimensions, are detailed for each separate form, but concise diagnostic analysis is entirely wanting. In the synopsis of species of Salmo given in the earlier work, "British and Irish Fishes," we find that the only trustworthy specific character differentiating *Salmo salar* from *Salmo trutta* is the presence in the former of eleven rows of scales in an oblique row from the adipose fin to the lateral line, all forms of *Salmo trutta* having fourteen or more of such scales. In the work before us one has to wade through two pages and a half of description of the salmon before reaching a mention of this diagnostic feature.

The views here expressed concerning the forms of sea-trout are somewhat different from those published in the "British and Irish Fishes." In the latter work Mr. Day described *Salmo trutta* and two varieties, *S. albus* and *S. cambricus*. In the present he describes *Salmo albus* (with the same synonymy) as the immature stage or grilse of the northern sea race of trout, *S. cambricus* being the southern sea race. Here again the want of a short diagnosis of the two races is much felt by the reader. From the numerical formulæ of the two races, which are separated by several pages, it is seen that the range of variation in the number of pyloric cæca in the one race is different from that in the other. In the northern form it is 33–61, in the southern 33–52. But it is extremely difficult, by reading and comparing the two lengthy descriptions, to discover what is the exact amount of difference between the two races. However,

after the descriptions we reach a discussion of this very point, and we find that most of the differences on which emphasis has been placed by other authorities are not found to be constant when a large number of specimens are examined, that the two races pass by gradual transition one into the other, but that as a rule in the southern there are fewer pyloric cæca than in the northern, and that the Sewin usually loses the teeth on the body of the vomer, at an earlier age than the northern sea trout.

The following are the different forms of non-migratory fresh-water trout which have been distinguished as distinct species, and whose synonymy is given in the present work: Brook trout, Lochleven trout, Crasspuill trout, Estuary trout, Orkney trout, Cornish trout, Great Lake trout, Gillaroo trout, and Swaledale trout. Short descriptions of these are given in footnotes, excepting the brook trout and the Lochleven trout, which are discussed at length in the text. These descriptions, though brief, are not diagnostic, and it requires the most careful reading and comparison to find in what respects the varieties differ from one another. Mr. Day believes that there is no definite line to be drawn between anadromous sea trout and non-migratory fresh-water trout, intermediate forms being common; nor between the different varieties of fresh-water trout. But granting—for we are inclined to agree with Mr. Day's conclusions—that in all these forms we have but one species, it is surely worth while to give a more lucid and more definite account of the differences between them. The arguments which Mr. Day employs to prove that all forms of trout, whether anadromous or confined to fresh water, belong to one species, may be divided into three classes, and his book would have been much easier to read if he had kept them separate. The first class are those which show that the various forms graduate into one another, or that the peculiarities of one are included in the range of variation of another; the second, those which show that removal to a different environment causes the characteristics of one form to be transmuted into those of another; the third, those which show that the several forms breed freely when crossed.

All the species of char which have been distinguished in Britain are considered in this book as belonging to one variable species which is identical with the *Salmo salvelinus*, Linn., and *S. umbla*, Linn ,—that is, with the Continental char. A similar criticism may be passed on Mr. Day's discussion of char to that made of his account of trout.

In the account of the American char, *Salmo fontinalis*, we have again a minute description, with no specific diagnosis. In a footnote to this portion of the work, it is pointed out that in the article "Salmonidæ" of the present edition of the "Encyclopædia Britannica" the erroneous statement of Dr. Günther, that the *Salmo namaycush* of America is a true trout, is repeated, but no reference is given to any work where the correct description of *S. namaycush* as a char can be found.

We have up to this point been criticizing Mr. Day's work chiefly from a speciegraphical point of view; we must now say a few words about the treatment of other branches of the subject. At the beginning of the account of the genus Salmo is a short description of the anatomy of Salmonoid fishes, followed by a discussion of the eggs and their development, the latter especially in connection with pisciculture at Sir J. Maitland's establishment at Howietoun. The description in the text of the mode of packing eggs which has been perfected at Howietoun seems to be erroneous: it is stated that the main principle is to employ thin layers of well-picked and pressed moss in trays with perforated bottoms, the eggs being separated from the moss by muslin mosquito netting, swan's down, calico, or butter cloth; while in a quotation in a footnote the correct account is given—namely, that the ova rest in direct contact with the damp moss, and are covered by another layer of the same, the muslin being only used in order that the layer of moss may be lifted and moved. Reference is made in this part of the book to the subject of hybridization between different species of Salmo, and a review of the history of the subject is given, but the full treatment of the subject occurs in a chapter specially devoted to it. In this chapter details are recorded of definite experiments in hybridization made at Howietoun. This chapter on hybrids is one of the most interesting in the book, and another on monstrosities is also well worth study.

Scattered throughout the pages are examples of that originality in sentence-construction which is familiar to all who know Mr. Day's writings. Thus in the account of artificial fertilization we read: "This is gently stirred with the hand until the eggs harden, or 'frees' as it is termed, being a period from one to three quarters of an hour according to the temperature, taking longest in cold weather." In another place we find: "One modifying circumstance in the feeding of the salmon has been observed to be connected with a muddy state of the river, possibly interfering with respiration, consequent upon the amount of mud which had been swallowed." Another passage which is worth quoting is:—"As regards thirst it would seem either to be unknown to these creatures; or, living as they do in a watery medium, it may be quenched by means of endosmosis through the skin. Were this not the case, it would be difficult to conceive how such a longing could be satisfied while residing in salt water."

But in spite of its defects the book contains a mass of new and accurate information concerning the forms of Salmonidæ of which it treats. In bibliography it is unusually rich, the results of previous writers being freely quoted in footnotes, so that several of the pages contain 90 per cent. of notes and only 10 per cent. of text. Besides the woodcuts in the course of the work, there are twelve plates of illustrations at the end, ten of which represent different forms of Salmonidæ in beautifully coloured lithographic impressions. The excellence of these is very great, and testifies to great care and skill on the part of the draughtsman (*i.e.* the author himself), the colourist, and the lithographer.

THE ECHINOIDEA.

Die Japanischen Seeigel. Von Dr. L. Döderlein. Pp. 59, Pl. I.-XI., Th. I., Fam. Cidaridæ and Saleniidæ. (Stuttgart: E. Schweizerbart'sche Verlagshandlung, E. Koch, 1887.)

DR. DÖDERLEIN has produced the first part of a very philosophical study of the beautiful Echinoidea, which are in their paradise in the Japanese seas. Some

collections of considerable importance came to Dr. Döderlein from private sources, and one was the result of the collecting during the expedition of the Italian corvette *Vettor Pisani*. Descriptions of some of the species of Cidaridæ, Temnopleuridæ, Saleniidæ, and of a species of Hemipedina were published by this author in *Wieg. Archiv*, 1885, v. 51, pp. 73–112, and as some of the forms had an ancient facies they attracted attention. Dr. Döderlein seems to have been impressed with the importance of the fauna in reference to the past, and prepared the way for the present publication by studying the pre-Jurassic and Cretaceous species of Cidaridæ especially. The work now publishing in parts will evidently be worthy of a good naturalist who sees no vast biological breaks in the continuity of the Cidaridæ since the appearance of the Zechstein Eocidaris, which he shows to be inseparable from the modern family Cidaridæ. The author describes the new species, reconsiders the Cidaridæ already known, pays especial attention to the growth of the structures which are used in classification, and, after describing some peculiar structures which he discovered in the St. Cassian Cidarids, passes on to subdivide the great genus so as to identify groups of species according to sub-genera in the Secondary and existing times. The descriptions of species are accompanied by fair illustrations, but it would be as well if more of the denuded tests could be shown.

There are four new species of Cidaris, a new Porocidaris, and three species of Goniocidaris; the depths from which the specimens were derived were from 40 to 200 fathoms. *Goniocidaris mikado*, Död., is the most extraordinary of the species, and has an unusually small number of coronal plates, characteristic median groovings, and wonderful spines—outdoing any other, and that is saying a good deal. The spines are essentially according to Japanese art: the larger have umbrella-shaped disks at their top, and some another disk lower down; the disks are circular in their deeply incised or occasionally serrate outline. The commonest species of Cidaris certainly puts one in mind of the Mediterranean *C. histrix* and of the North Atlantic *papillata*, but these Japanese forms are considered to belong to a different sub-genus by Dr. Döderlein. He was impressed with the fact that some striking Cretaceous Cidaridæ have the primary tubercles of some of the coronal plates near the apical system, aborted or wanting, and that a similar condition occurs in the majority of the Japanese species. He would establish a better definition for Stereocidaris, Pomel, and thus link the Cretaceous and Japanese species together. There is something very candid and straightforward in Dr. Döderlein's method of writing, and he does not hesitate to indicate how, in a comparatively short time, he altered his opinion regarding the particular sub-genus under which his own and other species should go. A similar state of things is well illustrated in the instance of A. Agassiz, and his synonymy of the Cidaridæ shows, as in the case of Dr. Döderlein, how a mind desirous of truth has to suffer in the attempt to subdivide a good genus into groups which are not founded upon differences of structures of much physiological importance.

As a matter of fact, the tubercles of *Cidaris* (*Stereocidaris*) *grandis*, and of the species *japonica*, Död., are not much more deficient than in many specimens of the common *Cidaris* (*Dorocidaris*) *papillata* of the North Atlantic and Mediterranean; and the shape and ornamentation of the coronal plates with ill-developed or absent primary tubercles, in the well-known *Cidaris sceptifera* from the upper chalk, do not resemble those of the modern forms. The ornamentation shown on Pl. II., Fig. 4, is more like that of a Tertiary Cidaroid from Sind than of the tall-plated Cretaceous type. But there is a decided resemblance between Dr. Döderlein's *C. sceptriferoides* and the Cretaceous species.

If these unsatisfactory sub-genera were simply used to represent groups of species linked together by some unimportant but readily recognized structural peculiarities, there would be no objection to be made—indeed, the proceeding is very useful; but the groups are allowed to become of generic significance, and thus it will be noticed at the conclusion of Dr. Döderlein's work, that a list of twenty-two groups equal to genera is given; and bad sub-genera, good ones, and good genera are jumbled up together. Good old Cidaris has in fact fallen to pieces.

In considering the species which have not a Japanese habitat, Dr. Döderlein is in opposition to A. Agassiz and De Loriol in reference to the proper sub-genus under which some well-known species are grouped, and it appears to be the case that Dr. Döderlein will have to arrange the species of Cidaris proper on his own lines.

The particular structure to which Dr. Döderlein alludes in noticing the Triassic Cidaridæ, is a horizontal groove on the interradial side of each pair of pores; it seems to be very universal; moreover, there is a more decided overlap and ribbing of the coronal plates in these pre-Jurassic forms than in the Jurassic and subsequent.

The Salenia described by Dr. Döderlein is a very close neighbour of *S. hastigera*, A. Ag.

Few monographs relating to the recent Echinoidea have as much good matter and logical reasoning in them as this one of Dr. Döderlein's, and the second part of the work will be looked for with great interest.

P. MARTIN DUNCAN.

FRITSCH'S PALÆONTOLOGICAL RESEARCHES.

Fauna der Gaskohle und der Kalksteine der Perm-formation, Böhmens. Von Dr. Ant. Fritsch. Band II., Heft 1, pp. 32, Plates 49–60. (Prague: In Commission bei Fr. Rivac, 1885.)

THE first part of this admirable work was briefly reviewed in NATURE, vol. xxi. p. 31. It was then observed that the book was almost as interesting to the stratigraphical geologist as to the palæontologist, for the Gaskohle and its superincumbent Kalksteine rest upon Silurian rocks, and are usually not covered by other strata in vertical succession. The coals, clays, and ironstones have a Carboniferous facies, and the conformable limestones are believed to be true Permians. The palæontological evidence regarding the age of the beds is somewhat anomalous in the views of purely British fossilists, but it speaks very forcibly and in a most suggestive manner to the students of the Gondwana formations of Hindustan. The presence of *Sigillaria*, *Stigmaria*, *Calamites*, and *Lepidodendra*, in the Gaskohle,

in association with Permian species of ferns and a *Walchia*, seems however to place these Bohemian beds on a lower geological horizon than the Gondwana series, which have had their palæobotany studied by the same palæontologist, Feistmantel, who investigated the plant-remains of the Permo-Carboniferous of Eastern Europe.

The rich fauna of Labyrinthodontia of the Gaskohle, which, as was explained, Fritsch prefers to study under the more comprehensive group of Stegocephali, is associated with fish of the genera *Ceratodus*, *Orthacanthus*, *Pleuracanthus*, *Acanthodes*, and *Amblypterus*, and also with many species of *Palæoniscus*, found elsewhere in true Permian beds. Amongst the Invertebrates are Arachnoidea, Julidæ, Estheriæ, and Anthracosiæ.

The part of the work now under consideration is palæontological, and refers to some of the most interesting of the many sculptured-headed, folded-toothed Amphibia which preceded the Reptilia in time. Several classificatory alterations, especially in the grouping of the genera in families, are introduced, and apparently with good reason; and at the commencement it will be noticed that the Microsaurii, Dawson, suffer, and a new family, the Dendrerpetontidæ, is founded. Fritsch considers that the structure of the teeth of such Microsaurs as *Hylonomus* and *Hylerpeton*, prevents their being associated in the same family with *Dendrerpeton*, the species of which have teeth strongly grooved from the base, with simple irregular folds, the top being smooth: the new family has, like the Microsaurs, amphicœlian vertebræ. It is certainly remarkable how widely these forms were distributed geographically during that long period when so much of the present continental areas was land. Fritsch describes two new species, and also a third about the generic position of which there may be some doubt, and which has a wonderful arrangement of cranial bones behind the orbits.

The most interesting parts of the work are now reached and the author comes to the consideration of those extraordinary Stegocephali which have such curious double and multiple developments of the vertebral centra. The first of the families of these groups is the Diplovertebridæ, and the solitary form of it is carefully described. The characters of the family are the doubly segmented vertebral centra, at the caudal end of the column, and a very decided pitting of the surfaces of the bones of the extremities for vascular canals.

Fritsch avails himself of Cope's terminology; and the peculiar condition of the vertebral centra—the anterior of the two segments carrying the spinous processes and the ribs, the posterior not having any relics of arches, and being plain—necessitates the arrangement of the species with those whose vertebræ are "embolomeri." The illustrations of the species on Plates 50 and 52 are admirable, and their comprehension is assisted by the woodcut diagrams placed in the context.

Sparagmites lacertinus, Fr., is placed amongst the Archægosauridæ, and it will be observed (Plate 50, Figs. 15, 16) how the vertebral centra differ from those of the last family. The centra appear to be broken up, and each has two lateral and an inferior component, coming under the division "rachitomi" of Cope. Miall's family Chauliodontia is represented in the Gaskohle by a species, and the preserved remains show the dissimilar teeth with a semi-Labyrinthodont structure; the genus included is a familiar one to English palæontologists, and is *Loxomma*. The last family, described in the book, has genera with highly developed crania and a parietal foramen (which also occurs in all these forms from the Gaskohle), and the vertebræ are even more remarkable than in the other families. In the Melosauridæ the caudal portion has the centra embolomerous, whilst those of the fore-part of the column are rachitomous; the teeth are dissimilar, and simply and irregularly folded. The supra-occipital bones occasionally have strongly developed, backward projecting, curved processes (*Sehnenhöckern*). The genus *Chelydosaurus*, with a well-developed tarsus and a most singular growth of chest and body plates, belongs to the family. *Sphenosaurus*, H. von Meyer, comes in here, and the species *S. Sternbergii*, elsewhere a Muschelkalk form, is found in the red sandstone of the Bohemian Permian! The new genus *Cochleosaurus* has a species which shows the posterior hooks of the supra-occipital bones in perfection.

The book which contains all this interesting matter will be found of great value by students as well as by advanced palæontologists, and the beauty of the illustrations leaves little to be desired. The Geological Society presented Dr. A. Fritsch with the Lyell Medal and Fund, and the gift was mainly owing to the appreciation of his excellent work amongst these Upper Palæozoic, Permo-Carb. fossils. The work is a great addition to the natural history of the early Vertebrata.

P. M. D.

OUR BOOK SHELF.

The Flora of Howth. By H. C. Hart (Dublin: Hodges, Figgis, and Co., 1887.)

MR. HART enthusiastically describes the parish of Howth as one with many attractions. He thinks that as a sea bathing summer retreat "its equal cannot be found in Ireland"; and he points out that it is invested with archæological interest by a great dolmen in the demesne of Lord Howth, by the ruins of an early abbey in the village of Howth, by the earlier church or chantry of St. Fintan's on the Sutton side, with its holy well, and by the ancient castle, called Corr Castle, of the Barons of Howth. A little way from the shore is Ireland's Eye, with the remains of a church of the sixth or seventh century. For the ornithologist, the entomologist, and the marine zoologist, Howth, according to Mr. Hart, provides much material for study. These things, however, he notes only by the way; it is with the flora of Howth that he is especially concerned. For this he claims attention on two grounds: (1) because several of the species found are rare; (2) because it does not often happen that so many forms exist in so small a space. Mr. Hart has taken great pains to make his account of his subject complete and readily intelligible, and the book ought to be of considerable service to local botanists and tourists.

Mineralogy. By Frank Rutley. Third Edition. (London: Thomas Murby, 1887.)

WE are glad to welcome a third edition of this excellent manual, which forms one of Murby's "Science and Art Department" series of text-books. The materials of the little work are arranged with great clearness, and the descriptions of minerals are invariably simple and precise. Nearly the whole of the chapter on crystallography has been re-written, and other alterations have been made to fit the book for the present requirements of students. More than fifty fresh woodcuts have been added.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*

"A Conspiracy of Silence."

MAY I ask your correspondents who have been good enough to read my article on "Darwin's Theory of Coral Islands," published in the September number of the *Nineteenth Century*, to begin addressing themselves to the merits of the scientific question there dealt with, and to cease wasting their own time and your space upon scolding me for a few words—perhaps exaggerated—respecting the wide-spread reluctance to question any theory advanced by Charles Darwin? I have already explained in your columns the sense in which I spoke, and, subject to that explanation, I have nothing to retract. I observe in Prof. Tait's notice of Dr. Balfour Stewart, published in your latest issue, a passage which shows that this very eminent man of science speaks in a tone very similar of certain "advanced" geologists who "ignore" views which "tend to dethrone" their own "pet theories." Moreover, since I last addressed you in explanation, I have observed the remarkable passage ("Darwin's Life," vol. ii. p. 186) in which my censor, Prof. Huxley, positively blasphemes against no less a distinguished body of scientific men than the French Institute for their conduct towards evolutionism. He speaks of the "ill-will of powerful members of that body producing for a long time the effect of a conspiracy of silence." This is the very same expression which I used, but without the offensive aggravations added by Prof. Huxley.

Inveraray, December 30, 1887. ARGYLL.

Mr. Seebohm on Physiological Selection.

FROM a footnote to page 23 of Mr. Seebohm's recently published and magnificent monograph on the Charadriidæ I learn that I owe him an apology for having inadvertently misrepresented his views upon a point of considerable importance in the philosophy of evolution. In his British Association paper (which he now re-publishes) he went even further than I had gone in recognizing the "swamping effects of intercrossing" upon incipient varieties, with the consequent importance of isolation in the differentiation of species. I therefore supposed that he likewise agreed with me in holding it improbable that new species arise as a result of many beneficial variations of the same kind arising at the same time and in the same place. I now find, however, that he is a strong advocate of the opposite opinion—apparently going further than Asa Gray, Nägeli, Mivart, the Duke of Argyll, or indeed any other evolutionist, in support of the doctrine of teleological variation in determinate lines. I therefore write to withdraw my previous misrepresentation of his views upon this matter, and to apologize for my inadvertency in making it.

At the same time, I may observe, it does not seem to me quite intelligible how Mr. Seebohm can reconcile his doctrine of teleological variation with his doctrine of the paramount importance of geographical isolation For it is evident that, in whatever measure geographical isolation is found to be of importance as a condition to the origin of species (*i.e.* by preventing free intercrossing), in that measure is the doctrine of teleological variation invalidated. Indeed, Mr. Seebohm himself puts Mr. Wallace on the horns of a dilemma with regard to a precisely parallel case. In order to meet me where I draw attention to the difficulty which free intercrossing imposes upon the theory of natural selection, Mr. Wallace argued in favour of collective variation, *i.e.* of the doctrine that a considerable percentage of identical and beneficial variations may arise simultaneously in the same community. Now, Mr. Seebohm very pertinently observes (p. 13):—"It seems to me that, by the admission of this fact, Mr. Wallace has dethroned his theory of natural selection from its proud position as the main factor in the origin of species." With this, of course, I fully agree; but does it not equally follow that by *his* admission of this same "fact" Mr. Seebohm is no less effectually dethroning his own theory of the paramount importance of isolation as one of the main factors in the origin of species?

In conclusion, I cannot understand why Mr. Seebohm should have ignored my answer to the criticisms which he now republishes. For, as I have pointed out in these columns before, the whole brunt of his criticism (like that of Mr. Wailace) was directed against a theory which never so much as occurred to me. Both my critics took it for granted that I supposed my "physiological complements" to arise only in pairs; and therefore they both had an easy case in showing how improbable it was that the two complements should chance to come together. But even in my original paper there were passages to show that I supposed these physiological variations to occur in large numbers, or "collectively," leading to what botanists now call "prepotency," and thus explaining why hybridization is so rare in Nature. Possibly in that paper I was not sufficiently explicit in guarding against a misconception which it never occurred to me could arise. But certainly in my reply to this misconception, no further doubt as to my meaning could possibly remain. I confess, therefore, to being not a little surprised at this reappearance of Mr. Seebohm's criticism, without allusion to my full repudiation of it a year ago. I should much like to learn his views upon the theory which I have published, but must protest against this absurd substitution being still attributed to me, after I have disclaimed it with all the emphasis of which the English language is capable. GEORGE J. ROMANES.

An Incorrect Footnote and its Consequences.

IN all the five editions of Baltzer's "Theorie und Anwendung der Determinanten" there stands at the foot of the first page an historical note, in which reference is made to a work entitled, "Demonstratio eliminationis Cramerianæ," by Mollweide (Leipzig, 1811). About a year ago it became necessary to examine this demonstration for the purpose of having it reported upon in an historical work. The University Libraries in Scotland were applied to in succession, but no copy could be heard of. Inquiries made at the more important libraries in Cambridge by friends resident there, or by letter, ended in the same unsatisfactory way. Letters, followed by an actual visit, to several libraries in London, brought no better result; and after every possible biographical scrap about Mollweide had been ferreted out in the British Museum, the suspicion began to form itself that some curious error had crept into Baltzer's footnote. In order to get to the bottom of the matter, the excellent mathematical library of Göttingen University was next applied to, and the library of Giessen University, where Baltzer was Professor; but in both cases in vain. A last effort was then made about a month ago in a letter to the University Library of Leipzig, where the reputed author Mollweide had taught, and where the "Demonstratio" (or *Demon*, as it had for more than one reason come to be called) had been published. Even here, at first, there was failure. But Prof. Virchl, who most kindly interested himself in the matter, was soon successful in his quest. What he found, however, was not a "Demonstratio" by Mollweide; the title was simply as follows: "Ad memoriam Kregelio-Sternbachianam in auditorio philosophorum die xviii. Julii, MDCCCXI. h. ix. celebrandam invitant ordinum Academiæ Lips. Decani seniores cæterique adsessores——'Demonstratio eliminationis Cramerianæ.'" Either, therefore, no author should have been mentioned by Baltzer, or an indication should have been given that Mollweide's name was an interpolation in the title. One or other of these courses would likewise have been less hurtful to Baltzer's reputation for accuracy; for, after all, Mollweide was not the author. In the Leipzig Library Catalogue the work is entered under the name of De Prasse, and Prof. Virchl had no doubt whatever, for perfectly conclusive reasons which he gave, that De Prasse was the author. The work extends to only 15 pages quarto, and is considered by the same authority to be very rare.

The point which we have now reached in the story might seem a not unfitting one to stop at; but the end is not yet. De Prasse's modesty requires explanation, and so likewise does the intrusion of Mollweide's name. Both are partly cleared up by the following facts supplied by Prof. Virchl. (1) The Kregel-Sternbach dissertation (which the "Demonstratio" was) falls to be delivered by the Dean of the Philosophical Faculty for the time being: the author's name was thus not an absolute necessity on the invitation title-page. (2) Mollweide was De Prasse's suc-

cessor, and came first to Leipzig in 1811, the very year we are concerned with; so that in that year both men may have held office, and consequently if an author's name had to be supplied Baltzer might easily have made a worse guess.

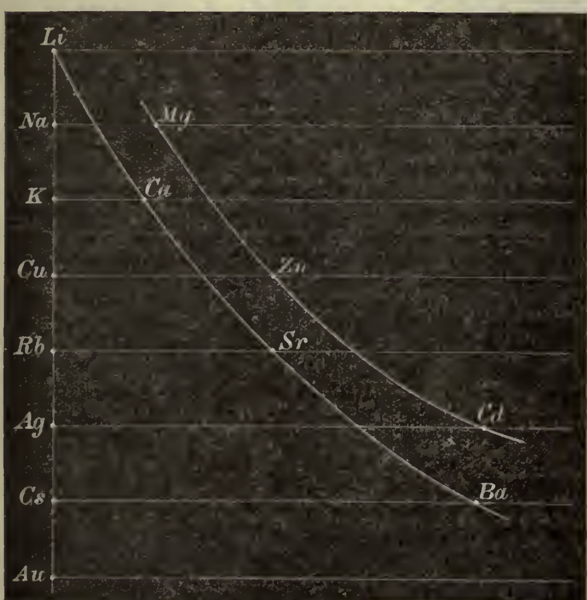
Both guess-work and circumstantial evidence, however, are quite unnecessary. After these facts were received from Leipzig, the library catalogue of University College, London, was turned up at De Prasse's name. No "Demonstratio," it is true, rewarded the searcher: but as a work with the miscellaneous-looking title, "Commentationes Mathematicæ," 4to, Lips. 1804–12, was found entered, the librarian was communicated with. In a day or two an obliging reply came to hand to the effect that the lair had indeed been found, the 15 quarto pages sought (or, at least, as many as are essential) being pp. 89–102 in the second fasciculus. The full title of the whole work is "Commentationes Mathematicæ, auctore Mauricio de Prasse, Math. prof. ord. in univers. liter. Lipsiensis." The first fasciculus contains 54 pages, and is dated 1804; the second contains 66 pages, viz. pp. 55–120, and is dated 1812. Of the eight separate "Commentationes" the "Demonstratio" is the seventh. Doubtless, copies of this collection of mathematical papers are to be found at several of the libraries above referred to. The work at any rate does not appear to be rare: the writer already possesses a copy, for which he paid the not extravagant sum of 2*s.* 8*d.*

The moral on the surface of this tale may be, "Verify your references"; it is not the only moral, however. Baltzer, in his first preface, felt called upon to direct attention to the many inaccuracies and even errors ("manche ungenauigkeiten und selbst unrichtigkeiten") of Spottiswoode's pioneer treatise; yet if the leaf following the said preface be turned over, a footnote of five lines is found containing five "ungenauigkeiten" (say), one of which—being that referred to in the narrative of the "Demon"—might well be put in a worse category. *Humanum est errare.* THOMAS MUIR.

Bothwell, Glasgow, December 26, 1887.

The Periodic Law.

IN none of the chemistry books or magazines to which I have access can I find any reference to a curious property of the chemical elements in connection with the Periodic Law. If instead of placing the elements as usual in seven vertical columns we arrange them at distances corresponding to the differences of their atomic weights, it will be found that they are disposed in curious curves. The following diagram will make my meaning



clearer. Arranging the monads in a vertical column, and taking it for a base line, place Ca at a distance from K corresponding to the difference of their atomic weights; also treat Sr and Ba in the same way in relation to Rb and Cs. It will then be found that they are arranged on a curve terminating in Li, which is known to unite in itself the properties of the metals of the alkalies and those of the alkaline earths. Mg, Zn, and Cd also range themselves on a curve when measured from Na, Cu, and Ag.

Ranging the tetrads vertically, we have O, S, Cr (Se?), and Mo, in almost a straight line, also P, V (As?), Nb and Sb. Many other curious relationships develop themselves if we plot off the elements vertically as well as horizontally. Is there any explanation of these curious curves? or is it simply accident? and if already known where can I find an account of them?

DONALD MURRAY.

Herald Office, Auckland, N.Z.

[Would not the position of Be (Beryllium) rather affect the apparent parallelism in these curves?—ED.]

The Leaps of *Lepus.*

WHILE rambling in the winter-time over the snow-covered plains in this region, I have recently interested myself in ascertaining how far, on a level surface, a hare or rabbit may leap at each spring, at a time when either of these animals is put to its best speed. Two species of *Lepus* are quite abundant in this vicinity, viz. the Mexican hare (*L. callotis callotis*), and the sage hare, which is really a medium-sized rabbit (*L. sylvaticus Nuttalli*), while the first-mentioned is a big hare. It is not uncommon to find here, in certain localities, a stretch of perfectly level prairie extending for a distance of 3 or 4 miles, and when this is covered by an even layer of 1 inch or more of snow, it offers an admirable surface on which to take account of the distance which may separate any two tracks of one of these animals, either one made by a hare or one made by one of the rabbits. On such a prairie as I have just referred to, I have on numerous occasions fired at these animals when they have been running, and at the same time beyond the range of my fowling-piece; such a shot almost invariably has the effect of so alarming the game as to make it run at its very best rate of speed, and, upon coming up with the tracks they have left on the snow at such times, I have been surprised at the distances they can clear at each individual leap. Under these conditions I once measured the spaces cleared by an old Mexican hare, and found the first two equalled 12 feet apiece, while the third effort was rather more than 13 feet, and I have never known this species to exceed this, although I have tested not a few of them. Of course the rabbit cannot compete with such magnificent gymnastics as this: it will, however, when thus frightened, make leaps of fully 6 feet; and on one occasion I measured one on the dead-level prairie, which was rather more than 7 feet. At their common rate of going, the hare rarely clears more than 4 feet at any single leap, while the rabbit is satisfied with rather more than 2 feet, and, when quietly feeding about the sage-brush, the tracks made by an individual of either species may actually overlap each other. Fort Wingate, New Mexico, December 6, 1887.

A NEW MAGNETIC SURVEY OF FRANCE.[1]

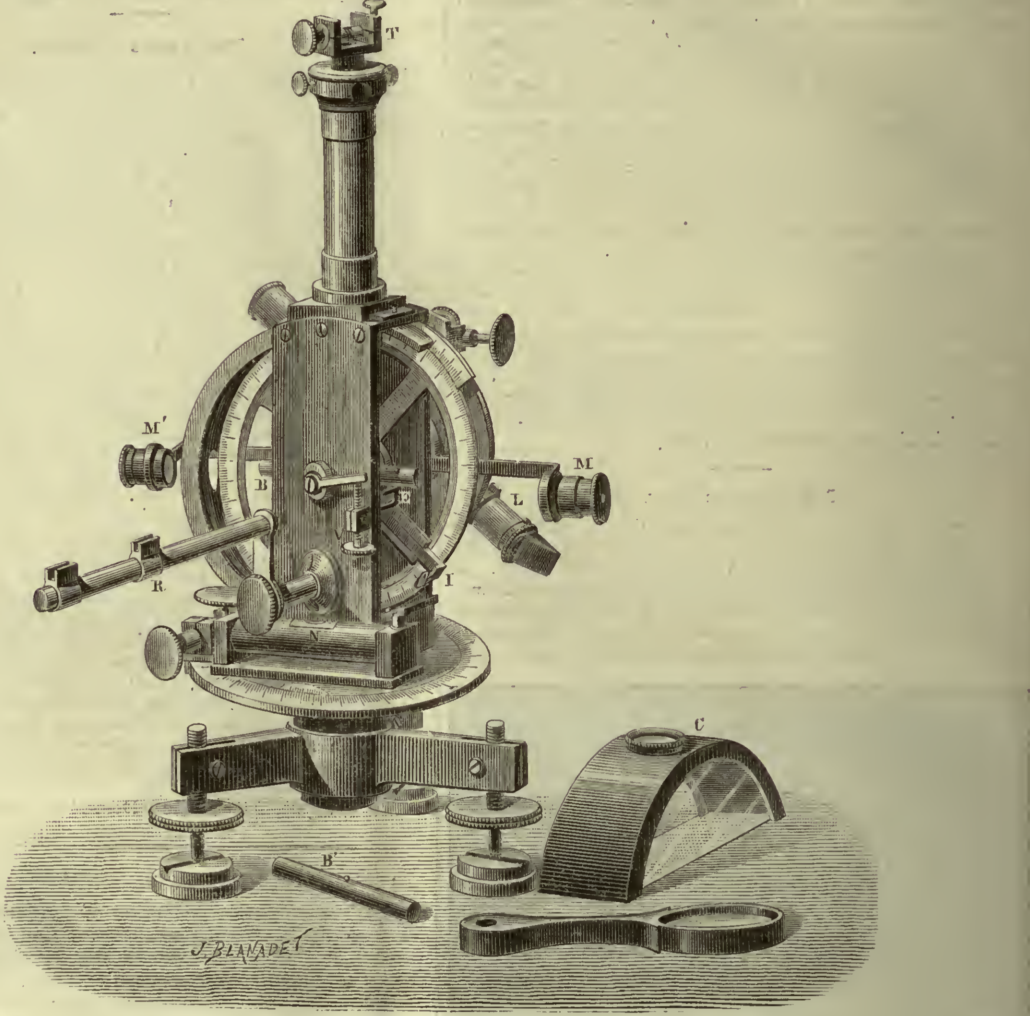
THE first systematic series of magnetic observations made in France was undertaken by Lamont, who in 1856 and 1857 determined the absolute value of the different elements at forty-four stations. The results are contained in his "Untersuchungen über die Richtung und Stärke der Erdmagnetismus an Verschiedenen Puncten des Südwestlichen Europa," and are reduced to three mean epochs: declination to March 1854; horizontal component to June 1848; and dip to the August of the same year. In 1868 and 1869 the Rev. Father Perry made a second series of observations of the intensity and direction of the earth's magnetic force at thirty-three stations in France (Phil. Trans., vols. clx. and clxii.). Determinations of declination have also been made at about twenty stations by MM. Marié-Davy and Descroix in 1875; and declination, dip, and intensity have been observed by M. de Bernardières at various points along

[1] "Détermination des Éléments Magnétiques en France." Ouvrage accompagné de nouvelles Cartes Magnétiques dressées pour le 1er Janvier. 1885 Par M. Th. Moureaux, Météorologiste-Adjoint au Bureau Central, Chargé du Service Magnétique à l'Observatoire du Parc Saint-Maur. (Paris: Gauthier-Villars, 1886.)

the Mediterranean littoral. These observations comprised all that was known respecting the distribution of the magnetic elements and rate of secular change in France prior to the appearance of the important work which forms the subject of this notice.

The observations of M. Moureaux were undertaken at the instigation of M. Mascart, the Director of the Meteorological Observatory of the Parc Saint Maur, and were made during the years 1884 and 1885. A few observations made in 1882 by M. Mascart and M. Moureaux in the neighbourhood of the Pyrenees are also included. A description of the instruments employed, of the methods of observation, together with a detailed account of the results obtained from about eighty stations, fairly well distributed over France, constitute the subject-matter of this memoir.

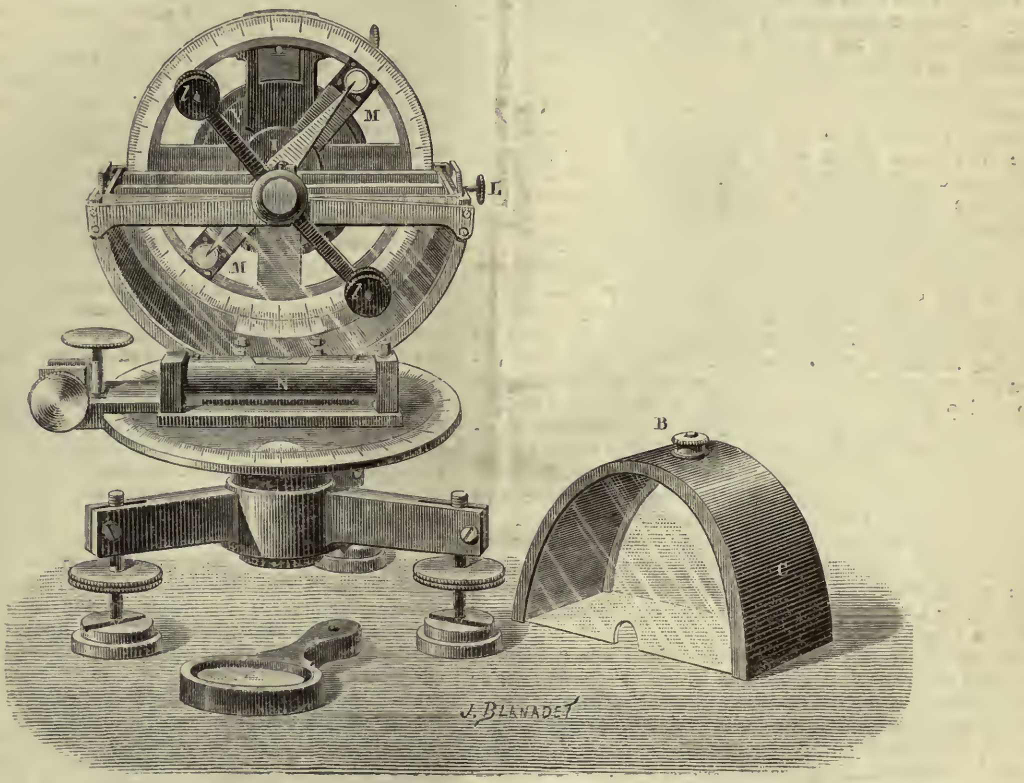
As the instruments employed by M. Moureaux differ in some important particulars from those which are ordinarily employed for field-work by us, it may be desirable to point out their peculiarities. The instruments which are mainly made use of in this country, and which have been employed by English observers who have made magnetic surveys in other parts of the world during the last quarter of a century, are of what is known as the Kew pattern,



Portable Magnetometer. B, magnet; E, apparatus for steadying magnet; N, level; M M', reading microscopes; L, telescope; T, torsion head; R, bar for deflection experiments.

and embody the results of the experience of such practical magneticians as Lloyd, Sabine, Airy, Welsh, Balfour Stewart, Whipple, and others. Indeed it may be said that almost every observer who has made any extensive series of measurements of terrestrial magnetism has influenced the construction of the Kew magnetometer, and there is no question that this instrument, although not absolutely perfect, has now reached a very high degree of excellence. In some respects, however, the magnetometer employed by M. Moureaux possesses advantages over the Kew pattern, and these are especially evident in surveys over rough and difficult country, and where the means of transport are limited. In the matter of weight alone there is a considerable difference. A Kew magnetometer, in its box complete, and exclusive of the deflection bar, which is now usually carried in a hollow leg of the tripod, weighs nearly 50 pounds, whereas that of the French observers weighs only about 9 pounds. A further advantage possessed by the French model is that it is also an alt-azimuth instrument, and hence the observer is less dependent upon the knowledge of true time, afforded by his chronometer, in determining the geographical meridian in a declination observation than he is with the English instrument. In the magnetic survey of Scotland made

by Welsh in 1857-58 it was necessary to make use of a special altazimuth instrument, or of a sextant and artificial horizon, in order to determine the sun's altitude at the time of observation, and a similar method was employed by the Rev. Father Perry in the course of the magnetic survey of France to which reference has already been made. Thanks to the admirable arrangement of our Post Office by which signals giving Greenwich mean time are sent to all the postal telegraph stations in the United Kingdom, it is possible for an observer engaged in magnetic work in the British Isles to determine the error and rate of his chronometer with an accuracy sufficient to enable him to dispense with the labour and trouble involved in the use of an altazimuth instrument. But unfortunately Greenwich mean time is not yet flashed all over the world, and a surveyor making use of the Kew magnetometer in distant countries would be under the necessity of making independent observations for solar altitude, and hence of adding to his *impedimenta* some such arrangement as those used in former surveys. Nor does this diminution in weight of the French instrument materially influence the accuracy of the observations, at all events so far as declination is concerned. It is hardly possible with the English instrument, even under favourable conditions, to obtain a declination observation which shall be accurate to within 2'. And yet, so far as an analysis of the data given by M. Moureaux enables us to judge, his instrument, of which the circle is only 0·08 m. in diameter, gives results which are in at least as close accordance with the truth. The method of observation which M. Moureaux adopts in determining the magnetic meridian allows him to read the position of both ends of the magnet both when erect and inverted in its stirrup. The magnets are solid and cylindrical in form, 6·5 cm. in length and 0·4 cm. in diameter, and weigh about 7½ grammes, and are suspended by a single thread



Iclinometer. M M, reading microscopes; L, lifting apparatus for needle; I, dipping needle; C, cover; N, level.

of silk 0·11 m. in length. The ends of the magnets are made slightly concave, and are polished so as to reflect the cross-wire placed in each of the microscopes, through which the readings for position are made. Each determination of geographical meridian is the mean result of from four to six independent observations, which rarely differ among themselves by more than 1' of arc.

The same magnet which serves for the observation of declination is used as in the Kew instrument for the determination of the horizontal component, which is done, as with us, by finding the relation $\frac{H}{M}$ by Gauss's method of deflections, and the product HM by the method of vibrations, whence H can be deduced. For this particular determination it seems to us that the Kew model is distinctly to be preferred. Indeed, in the observation of deflections the Kew instrument leaves very little to be desired, provided that care is taken to avoid sudden alterations of temperature, say by exposure to sunshine. The main error in the estimation of the period of vibration of the magnet also arises from the uncertainty of its temperature when observing in the field. But in the French instrument no special pains are taken either to ascertain or to correct for temperature. M. Moureaux indeed is of opinion that under the conditions of observation, the error committed by neglecting the correction is not greater than that which results from the difficulty of knowing whether the temperature of the magnet is represented by that of the outside thermometer. This is no doubt true of the instrument employed by the French observer, but in the Kew pattern special attention is paid to this point, and, although the arrangement leaves something to be desired, there is no doubt that with care the temperature may be determined with a fairly close

approximation to truth. Moreover, the method of determining the time of vibration of the magnet as generally practised by English observers also appears to us to be preferable to that adopted by M. Moureaux, although this has the advantage of occupying little time and therefore of minimizing the effect of any alteration in temperature during these observations and those of the deflections.

As regards inclination, there can, we think, be little doubt that the Kew pattern of dip circle, as made by Dover, is distinctly preferable to that used in the French survey. Indeed in the latter instrument it would seem to be difficult to avoid draughts and dust, the two great enemies to accuracy in field work. Only one needle of 0·065 m. in length was used by M. Moureaux, and the memoir gives no direct evidence of the degree of accuracy of which it was capable. Still M. Moureaux's instrument has the merit of portability, since, when packed in its box, it weighs less than 2 kilos.

As regards the plan of operations, we cannot speak too highly. Every care seems to have been taken, by a preliminary study of the ground, to select stations which should be as free as possible from any local disturbance, such as the proximity of railway-lines, manufactories, &c. It would, however, have added to the completeness of M. Moureaux's work if to the description of the stations there had been given some account of their general geological character and of that of the districts in the immediate neighbourhood, since, as is well known, the presence of igneous rocks or of rocks containing magnetic oxide of iron is the chief cause of local disturbance.

M. Moureaux began operations at each station, as a rule, at the commendably early hour of 7 a.m., so as to secure the determination of the magnetic meridian when the diurnal variation in declination was at about its morning minimum and nearly stationary. The observations for the geographical meridian were made between 8.30 and 9 a.m.; that is, at about the best period for the observation. The determination of the horizontal component was next made, a set of swings being taken before and after the deflection observations, all of which were completed by about 10.30 a.m. Between this time and noon was occupied in the dip observations. When the circumstances of travel or of weather made a departure from this plan necessary, the observations of declination were made either at the time of maximum of diurnal variation or at about the time of evening minimum—say between 5 and 6 p.m.

The results of the various observations are presented with that elegance and clearness which is characteristic of the publications of the Bureau Central Météorologique. They are all referred to the Parc Saint-Maur as a base station, by direct comparisons with the photographic curves of the registering apparatus at work in the magnetic observatory; and are reduced to the mean epoch January 1, 1885, by adding the difference between the values obtained at the different stations and Parc Saint-Maur at the time of observation to the corresponding values at Parc Saint-Maur on January 1, 1885, obtained from the mean of the observations made there in December 1884 and January 1885. This method presupposes that the diurnal variation is of the same order throughout the whole of France, which is not strictly true, but the error resulting from this mode of treatment is probably not greater than the errors of the observations themselves.

The final values are then tabulated and compared with the values obtained for the same places as deduced from the curves given by Lamont, and in this way a measure of the secular change is obtained. The results are finally plotted in the form of maps on Mercator's projection, giving lines of equal declination, force (horizontal component), and dip, and there is, lastly, a map of magnetic meridians. As to the methods employed in the construction of these maps there are unfortunately no details. It would seem that the lines are simply free-hand curves, so drawn as to best represent the observational results. There is at least no evidence that the results have been combined, as is the practice among English magneticians, so as to obtain the most probable direction of the lines by calculation, and therefore independently of bias on the part of the map-maker. M. Moureaux moreover offers us no direct means of comparing the values as taken out from his curves with the actual values obtained at the various stations. The maps, however, show certain points of interest which may be thus briefly summarized:—

(1) In the north of France the declination varies about 30′ for each degree of longitude; this proportion decreases in the south. The difference in declination between two points at a given distance apart on the same parallel increases with the latitude, and the isogonal lines are closer together in the north than in the south. The most remarkable feature in the declination map is the form of the curves in Brittany and more especially in the neighbourhood of Rennes. Their regularity is broken in such manner as to suggest that they are modified by the particular trend of the coast-line. Throughout the whole of the north-west portion of France the declination is less than would be expected from the direction and character of the lines over the rest of the Continent. A comparison with Lamont's map for 1854 shows that the declination has diminished during the thirty years by about 3° 58′ in the north, and by about 3° 19′ in the south of France. The mean annual decrease in declination seems to increase pretty regularly from south-south-east to north-north-west, or in a direction approximating to that of the magnetic north; hence the curves of equal declination have not been displaced, by time, parallel to themselves, but have gradually approached to the direction of the geographical meridian.

(2) The map of lines of equal horizontal component shows that the minimum, 0·18460 (C.G.S. units), is observed at Dunkirk, and the maximum, 0·22124, at Perpignan, or a difference of 0·03664 for the interval of 8° of latitude which separates the two points. The maximum rate of decrease of the horizontal component takes place in a direction approximating to that of the magnetic meridian. The decrease is more rapid in the south than in the north, and the interval between two consecutive curves increases pretty regularly with the latitude. The direction of these lines, like those of declination, seems to be modified towards the north-west of France, in such manner that the line corresponding to 0·190 is nearly straight and does not bend to the south as do the others. At places in the extreme north-west of France the value of the horizontal component is therefore greater than the general direction of the other lines would indicate should be the case. A comparison with Lamont's map for 1848 shows that the horizontal component has increased from about 0·008 to 0·010 in absolute value during the thirty-six years. The lines of equal horizontal component have not been displaced parallel to themselves, but are more inclined towards the east, so as to approach the direction of the geographical parallels. The secular change is at its maximum in the west, and diminishes slightly towards the east.

(3) The map of isoclinals shows that these lines have sensibly the same orientation as the lines of equal horizontal component; *i.e.* these are very nearly normal to the direction of the magnetic needle. Whilst the inclination diminishes in general towards the south, the interval between two consecutive curves decreases pretty regularly with the latitude. The direction of the lines corresponding to 66° and 67° seems to be slightly modified as they cross the north-west part of France, as are the lines of equal horizontal component. During the thirty-six years which have intervened since the date of Lamont's map, the dip has decreased by about 1° 35′ in

the north and by about 2° in the south, and, like the lines of horizontal component, the isoclinals have not been displaced parallel to themselves, but in a direction approximating to that of the parallels of latitude. The secular change is least in the north east and gradually increases towards the south, and attains its maximum along the Pyrenees and towards the Gulf of Genoa.

M. Moureaux is to be congratulated on the results of his work, for his countrymen have hitherto scarcely contributed their fair share to our knowledge of terrestrial magnetism. Even the surveys of their own country have been made for them by Germans and Englishmen. Now that Frenchmen themselves have made a beginning, it is to be hoped that the continuity of the work will not be interrupted, for it is only by systematic survey work of the kind so successfully accomplished by M. Moureaux that our knowledge of the magnetic state of the earth and of the laws which regulate its changes can be elucidated.

T. E. THORPE.

TIMBER, AND SOME OF ITS DISEASES.[1]

IV.

BEFORE proceeding further it will be of advantage to describe another tree-killing fungus, which has long been well known to mycologists as one of the commonest of our toadstools growing from rotten stumps, and decaying wood-work such as old water-pipes, bridges, &c. This is *Agaricus melleus* (Fig. 15), a tawny yellow toadstool with

FIG. 15.—A small group of *Agaricus* (*Armillaria*) *melleus*. The toad-stool is tawny-yellow, and produces white spores; the gills are decurrent, and the stem bears a ring. The fine hair-like appendages on the pileus should be bolder.

a ring round its stem, and its gills running down on the stem and bearing white spores, and which springs in tufts from the base of dead and dying trees during September and October. It is very common in this country, and I have often found it on beeches and other trees in Surrey, but it has been regarded as simply springing from the dead rotten wood, &c., at the base of the tree. As a matter of fact, however, this toadstool is traced to a series of dark shining strings, looking almost like the purple-black leaf-stalks of the maidenhair fern, and these strings branch and meander in the wood of the tree, and in the soil, and may attain even great lengths—several feet, for instance. The interest of all this is enhanced when we know that until the last few years these long black cords were supposed to be a peculiar form of fungus, and were known as *Rhizomorpha*. They are, however, the subterranean vegetative parts (mycelium) of the Agaric we are concerned with, and they can be traced without break of continuity from the base of the toadstool into the soil and tree (Fig. 16). I have several times followed these dark mycelial cords into the timber of old beeches and spruce-fir stumps, but they are also to be found in oaks, plums, various Conifers, and probably may occur in most of our timber-trees if opportunity offers.

The most important point in this connection is that *Agaricus melleus* becomes in these cases a true parasite,

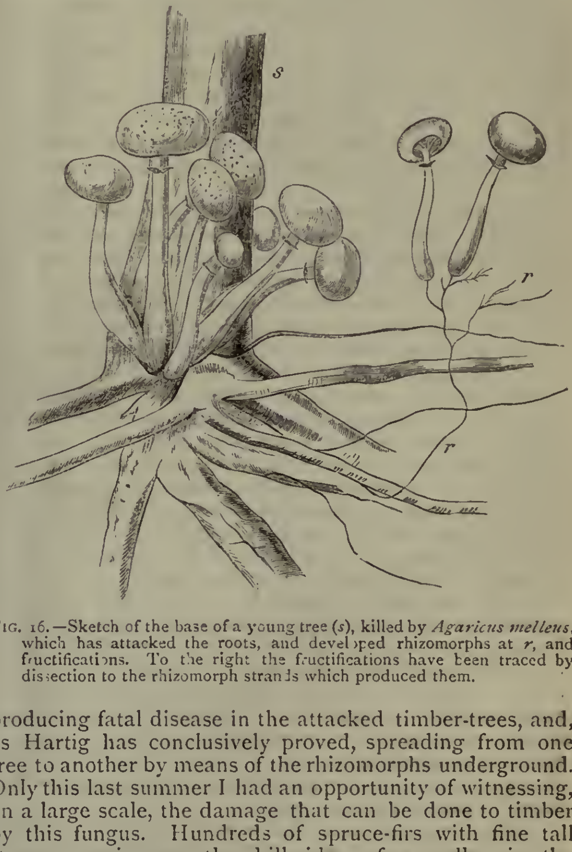


FIG. 16.—Sketch of the base of a young tree (*s*), killed by *Agaricus melleus*, which has attacked the roots, and developed rhizomorphs at *r*, and fructifications. To the right the fructifications have been traced by dissection to the rhizomorph strands which produced them.

producing fatal disease in the attacked timber-trees, and, as Hartig has conclusively proved, spreading from one tree to another by means of the rhizomorphs underground. Only this last summer I had an opportunity of witnessing, on a large scale, the damage that can be done to timber by this fungus. Hundreds of spruce-firs with fine tall stems, growing on the hill sides of a valley in the Bavarian Alps, were shown to me as "victims to a kind of rot." In most cases the trees (which at first sight appeared only slightly unhealthy) gave a hollow sound when struck, and the foresters told me that nearly every tree was rotten at the core. I had found the mycelium of *Agaricus melleus* in the rotting stumps of previously felled trees all up and down the same valley, but it was not satisfactory to simply assume that the "rot" was the same in both cases, though the foresters assured me it was so.

By the kindness of the forest manager I was allowed to fell one of these trees. It was chosen at hazard, after the men had struck a large number, to show me how easily the hollow trees could be detected by the sound.

[1] Continued from p. 229.

The tree was felled by sawing close to the roots: the interior was hollow for several feet up the stem, and two of the main roots were hollow as far as we could poke canes, and no doubt further. The dark-coloured rotting mass around the hollow was wet and spongy, and consisted of disintegrated wood held together by a mesh-work of the rhizomorphs. Further outwards the wood was yellow, with white patches scattered in the yellow matrix, and, again, the rhizomorph-strands were seen running in all directions through the mass.

Not to follow this particular case further—since we are concerned with the general features of the diseases of timber—I may pass to the consideration of the diagnosis of this disease caused by *Agaricus melleus*, as contrasted with that due to *Trametes radiciperda*.

Of course no botanist would confound the fructification of the *Trametes* with that of the *Agaricus;* but the fructifications of such fungi only appear at certain seasons, and that of *Trametes radiciperda* may be underground, and it is important to be able to distinguish such forms in the absence of the fructifications.

The external symptoms of the disease, where young trees are concerned, are similar in both cases. In a plantation at Freising, in Bavaria, Prof. Hartig showed me young Weymouth pines (*P. Strobus*) attacked and killed by *Agaricus melleus*. The leaves turn pale and yellow, and the lower part of the stem—the so-called "collar"—begins to die and rot, the cortex above still looking healthy. So far the symptoms might be those due to the destructive action of other forms of tree-killing fungi.

On uprooting a young pine, killed or badly attacked by the Agaric, the roots are found to be matted together with a ball of earth permeated by the resin which has flowed out: this is very pronounced in the case of some pines, less so in others. On lifting up the scales of the bark, there will be found, not the silky, white, delicate mycelium of the *Trametes*, but probably the dark cord-like rhizomorphs: there may also be flat white rhizomorphs in the young stages, but they are easily distinguished. These dark rhizomorphs may also be found spreading around into the soil from the roots, and they look so much like thin roots indeed that we can at once understand their name—rhizomorph. The presence of the rhizomorphs and (in the case of the resinous pines) the outflow of resin and sticking together of soil and roots are good distinctive features. No less evident are the differences to be found on examining the diseased timber, as exemplified by Prof. Hartig's magnificent specimens. The wood attacked assumes brown and bright yellow colours, and is marked by sharp brown or nearly black lines, bounding areas of one colour and separating them from areas of another colour. In some cases the yellow colour is quite bright—canary yellow, or nearly so. The white areas scattered in this yellow matrix have no black specks in them, and can thus be distinguished from those due to the *Trametes*. In advanced stages the purple-black rhizomorphs will be found in the soft, spongy wood.

The great danger of *Agaricus melleus* is its power of extending itself beneath the soil by means of the spreading rhizomorphs: these are known to reach lengths of several feet, and to pass from root to root, keeping a more or less horizontal course at a depth of 6 or 8 inches or so in the ground. On reaching the root of another tree, the tips of the branched rhizomorph penetrate the living cortex, and grow forward in the plane of the cambium, sending off smaller ramifications into the medullary rays and (in the case of the pines, &c.) into the resin passages. The hyphæ of the ultimate twigs enter the tracheides, vessels, &c., of the wood, and delignify them, with changes of colour and substance as described. Reference must be made to Prof. Hartig's publications for the details which serve to distinguish histologically between timber attacked by *Agaricus melleus* and by *Trametes* or other fungi. Enough has been said to show that diagnosis is possible, and indeed, to an expert, not difficult.

It is at least clear from the above sketch that we can distinguish these two kinds of diseases of timber, and it will be seen on reflection that this depends on knowledge of the structure and functions of the timber and cambium on the one hand, and proper acquaintance with the biology of the fungi on the other. It is the victory of the fungus over the timber in the struggle for existence which brings about the disease; and one who is ignorant of these points will be apt to go astray in any reasoning which concerns the whole question. Anyone knowing the facts and understanding their bearings, on the contrary, possesses the key to a reasonable treatment of the timber; and this is important, because the two diseases referred to can be eradicated from young plantations and the areas of their ravages limited in older forests.

Suppose, for example, a plantation presents the following case. A tree is found to turn sickly and die, with the symptoms described, and trees immediately surrounding it are turning yellow. The first tree is at once cut down, and its roots and timber examined, and the diagnosis shows the presence of *Agaricus melleus* or of *Trametes radiciperda*, as the case may be. Knowing this, the expert also knows more. If the timber is being destroyed by the *Trametes*, he knows that the ravaging agent can travel from tree to tree by means of roots in contact, and he at once cuts a ditch around the diseased area, taking care to include the recently-infected and neighbouring trees. Then the diseased timber is cut, because it will get worse the longer it stands, and the diseased parts burnt. If *Agaricus melleus* is the destroying agent, a similar procedure is necessary; but regard must be had to the much more extensive wanderings of the rhizomorphs in the soil, and it may be imperative to cut the moat round more of the neighbouring trees. Nevertheless, it has also to be remembered that the rhizomorphs run not far below the surface. However, my purpose here is not to treat this subject in detail, but to indicate the lines along which practical application of the truths of botanical science may be looked for. The reader who wishes to go further into the subject may consult special works. Of course the spores are a source of danger, but need be by no means so much so where knowledge is intelligently applied in removing young fructifications.

I will now pass on to a few remarks on a class of disease-producing timber fungi which present certain peculiarities in their biology. The two fungi which have been described are true parasites, attacking the roots of living trees, and causing disease in the timber by travelling up the cambium, &c., into the stem: the fungi I am about to refer to are termed wound-parasites, because they attack the timber of trees at the surfaces of wounds, such as cut branches, torn bark, frost-cracks, &c., and spread from thence into the sound timber. When we are reminded how many sources of danger are here open in the shape of wounds, there is no room for wonder that such fungi as these are so widely spread. Squirrels, rats, cattle, &c., nibble or rub off bark; snow and dew break branches; insects bore into stems; wind, hail, &c., injure young parts of trees; and in fact small wounds are formed in such quantities that if the fructifications of such fungi as those referred to are permitted to ripen indiscriminately, the wonder is not that access to the timber is gained, but rather that a tree of any considerable age escapes at all.

One of the commonest of these is *Polyporus sulphureus*, which does great injury to all kinds of standing timber, especially the oak, poplar, willow, hazel, pear, larch, and others. It is probably well known to all foresters, as its fructification projects horizontally from the diseased trunks as tiers of bracket-shaped bodies of a cheese-like

consistency; bright yellow below, where the numerous minute pores are, and orange or somewhat vermilion above, giving the substance a coral-like appearance. I have often seen it in the neighbourhood of Englefield Green and Windsor, and it is very common in England generally.

If the spore of this *Polyporus* lodges on a wound which exposes the cambium and young wood, the filaments grow into the medullary rays and the vessels, and soon spread in all directions in the timber, especially longitudinally, causing the latter to assume a warm brown colour and to undergo decay. In the infested timber are to be observed radial and other crevices filled with the dense felt-like mycelium formed by the common growth of the innumerable branched filaments. In bad cases it is possible to strip sheets of this yellowish white felt-work out of the cracks, and on looking at the timber more closely (of the oak, for instance) the vessels are found to be filled with the fungus filaments, and look like long white streaks in longitudinal sections of the wood—showing as white dots in transverse sections.

It is not necessary to dwell on the details of the histology of the diseased timber: the ultimate filaments of the fungus penetrate the walls of all the cells and vessels, dissolve and destroy the starch in the medullary rays, and convert the lignified walls of the wood elements back again into cellulose. This evidently occurs by some solvent action, and is due to a ferment excreted from the fungus filaments, and the destroyed timber becomes reduced to a brown mass of powder.

I cannot leave this subject without referring to a remarkably interesting museum specimen which Prof. Hartig showed and explained to me this summer. This is a block of wood containing an enormous irregularly spheroidal mass of the white felted mycelium of this fungus, *Polyporus sulphureus*. The mass had been cut clean across, and the section exposed a number of thin brown ovoid bodies embedded in the closely-woven felt: these bodies were of the size and shape of acorns, but were simply hollow shells filled with the same felt-like mycelium as that in which they were embedded. They were cut in all directions, and so appeared as circles in some cases. These bodies are, in fact, the outer shells of so many acorns, embedded in and hollowed out by the mycelium of *Polyporus sulphureus*. Hartig's ingenious explanation of their presence speaks for itself. A squirrel had stored up the acorns in a hollow in the timber, and had not returned to them—what tragedy intervenes must be left to the imagination. The *Polyporus* had then invaded the hollow, and the acorns, and had dissolved and destroyed the cellular and starchy contents of the latter, leaving only the cuticularized and corky shells, looking exactly like fossil eggs in the matrix. I hardly think geology can beat this for a true story.

The three diseases so far described serve very well as types of a number of others known to be due to the invasion of timber and the dissolution of the walls of its cells, fibres, and vessels by Hymenomycetous fungi, *i.e.* by fungi allied to the toadstools and polypores. They all "rot" the timber by destroying its structure and substance, starting from the cambium and medullary rays.

To mention one or two additional forms, *Trametes Pini* is common on pines, but, unlike its truly parasitic ally, *Tr. radiciperda*, which attacks sound roots, it is a wound-parasite, and seems able to gain access to the timber only if the spores germinate on exposed surfaces. The disease it produces is very like that caused by its ally: probably none but an expert could distinguish between them, though the differences are clear when the histology is understood.

Polyporus fulvus is remarkable because its hyphæ destroy the middle-lamella, and thus isolate the tracheides in the timber of firs; *Polyporus borealis* also produces disease in the timber of standing Conifers; *Polyporus igniarius* is one of the commonest parasites on trees such as the oak, &c., and produces in them a disease not unlike that due to the last form mentioned; *Polyporus dryadeus* also destroys oaks, and is again remarkable because its hyphæ destroy the middle-lamella.

With reference to the two fungi last mentioned I cannot avoid describing a specimen in the Museum of Forest Botany in München, since it seems to have a possible bearing on a very important question of biology, viz. the action of soluble ferments.

It has already been stated that some of these tree-killing fungi excrete ferments which attack and dissolve starch-grains, and it is well known that starch-grains are stored up in the cells of the medullary rays found in timber. Now, *Polyporus dryadeus* and *P. igniarius* are such fungi; their hyphæ excrete a ferment which completely destroys the starch-grains in the cells of the medullary rays of the oak, a tree very apt to be attacked by these two parasites, though *P. igniarius*, at any rate, attacks many other dicotyledonous trees as well. It occasionally happens that an oak is attacked by both of these Polyporei, and their mycelia become intermingled in the timber: when this is the case the *starch-grains remain intact in those cells which are invaded simultaneously by the hyphæ of both fungi*. Prof. Hartig lately showed me longitudinal radial sections of oak-timber thus attacked, and the medullary rays showed up as glistening white plates. These plates consist of nearly pure starch: the hyphæ have destroyed the cell-walls, but left the starch intact. It is easy to suggest that the two ferments acting together exert (with respect to the starch), a sort of inhibitory action one on the other; but it is also obvious that this is not the ultimate explanation, and one feels that the matter deserves investigation.

It now becomes a question—What other types of timber-diseases shall be described? Of course the limits of a popular article are too narrow for anything approaching an exhaustive treatment of such a subject, and nothing has as yet been said of several other diseases due to crust-like fungi often found on decaying stems, or of others due to certain minute fungi which attack healthy roots. Then there is a class of diseases which commence in the bark or cortex of trees, and extend thence into the cambium and timber: some of these "cankers," as they are often called, are proved to be due to the ravages of fungi, though there is another series of apparently similar "cankers" which are caused by variations in the environment—the atmosphere and weather generally.

It would need a long article to place the reader *au courant* with the chief results of what is known of these diseases, and I must be content here with the bare statement that these "cankers" are in the main due to local injury or destruction of the cambium. If the normal cylindrical sheet of cambium is locally irritated or destroyed, no one can wonder that the thickening layers of wood are not continued normally at the locality in question: the uninjured cells are also influenced, and abnormal cushions of tissue formed which vary in different cases. Now, in "cankers" this is—put shortly—what happens: it may be, and often is, due to the local action of a parasitic fungus; or it may be—and, again, often is—owing to injuries produced by the weather, in the broad sense, and saprophytic organisms may subsequently invade the wounds.

The details as to how the injury thus set up is propagated to other parts—how the "canker" spreads into the bark and wood around—*are* details, and would require considerable space for their description: the chief point here is again the destructive action of mycelia of various fungi, which by means of their powers of pervading the cells and vessels of the wood, and of secreting soluble ferments which break down the structure of the timber, render the latter diseased and unfit for use. The only too well known larch-disease is a case in point; but, since

this is a subject which needs a chapter to itself, I may pass on to more general remarks on what we have learnt so far.

It will be noticed that, whereas such fungi as *Trametes radiciperda* and *Agaricus melleus* are true parasites which can attack the living roots of trees, the other fungi referred to can only reach the interior of the timber from the exposed surfaces of wounds. It has been pointed out along what lines the special treatment of the former diseases must be followed, and it only remains to say of the latter: take care of the cortex and cambium of the tree, and the timber will take care of itself. It is unquestionably true that the diseases due to wound-parasites can be avoided if no open wounds are allowed to exist. Many a fine oak and beech perishes before its time, or its timber becomes diseased and a high wind blows the tree down, because the spores of one of these fungi alight on the cut or torn surface of a pruned or broken branch. Of course it is not always possible to carry out the surgical operations, so to speak, which are necessary to protect a tree which has lost a limb, and in other cases no doubt those responsible have to discuss whether it costs more to perform the operations on a large scale than to risk the timber. With these matters I have nothing to do here, but the fact remains that by properly closing over open wounds, and allowing the surrounding cambium to cover them up, as it will naturally do, the term of life of many a valuable tree can be prolonged, and its timber not only prevented from becoming diseased and deteriorating, but actually increased in value.

There is no need probably for me to repeat that, although the present essay deals with certain diseases of timber due to fungi, there are other diseases brought about entirely by inorganic agencies. Some of these were touched upon in the last article, and I have already put before the readers of NATURE some remarks as to how trees and their timber may suffer from the roots being in an unsuitable medium.

In the next paper it is proposed to deal with the so-called "dry-rot" in timber which has been felled and cut up—a disease which has produced much distress at various times and in various countries.

H. MARSHALL WARD.

(*To be continued.*)

PERPETUAL MOTION.[1]

IF we study the past in order to trace the development of machines, we cannot help being astonished at the long centuries during which man was content to employ only his own muscular effort and that of animals, instead of utilizing the other forces of Nature to do his work; for it is a striking fact that it is during little more than the last quarter of a century that the power of the steam-engine has in the aggregate become twice as great as that of the whole working population of the world.

Although the early history of the subject is shrouded in obscurity, there is little doubt that the power of water was the first to be employed. We can easily imagine that, in those early days when the laws of Nature were so little understood, the idea would arise that, if some machine could be contrived which would not get tired like man or animal, as machines appeared to do when left to themselves, and, moreover, one which did not depend upon a capricious and variable supply of water, such a machine would go on for ever—in short, would have perpetual motion. As a matter of fact, Geiger, the German philologist, has adduced strong grounds for believing the Buddhist praying-wheels—on which the prayers of the worshippers were fastened, and which were turned by water power—to be probably the first kind of water motor; and at the same time the first record of a proposal for a perpetual motion machine appears to be in the "Siddhânta Ciromani," a Sanskrit text-book on astronomy, in which a wheel for this purpose is suggested, having a number of closed equidistant holes half filled with mercury upon a zigzag line round its rim. No doubt other suggestions of this kind were made from time to time, but writers and literary men did not condescend to notice them, or even the progress of the really practical and useful machines. We are thus brought from that distant date down to the thirteenth century, when we find in the sketch-book of an architect, Wilars de Honecort (the original being now in the École des Chartres, at Paris), a drawing of a proposed perpetual motion machine, with the statement which, translated, runs:—"Many a time have skilful workmen tried to contrive a wheel that shall turn of itself: here is a way to make such by means of an uneven number of mallets or by quicksilver." The engraving shows four mallets upon what is evidently meant to be the descending side of the wheel, and three upon the ascending side, the former therefore overbalancing the latter. To get the mallets into this desirable position the top one on the descending side has evidently been made to fall over before its time; but independently of this there is to the ordinary mind a strong suggestion of speedy dissolution in any structure a greater number of whose parts are going in one direction than in the other, but this little difficulty M. de Honecort does not allude to or discuss. The unevenly weighted wheel in which the action of gravity is to be cheated in some way or the other has appeared in a great variety of forms since, and, from the words "many a time," probably before, and is by far the most important type of proposed contrivance for perpetual motion.

About two centuries after De Honecort, the famous Leonardi da Vinci gives sketches of six designs, either due to his own fertile brain or taken from other sources, and since then there has been an incessant flow of proposals of this type of machine, a large number of which are given in the work of Dr. Henry Dirks, "Perpetuum Mobile," and several in vol. xii. of the *Mechanical World*.

The next class of proposed machines we may consider are those in which gravity was to be made use of in one direction and evaded in the opposite, by the agency of falling water, amongst these being the devices of Schott, Scheiner, Böckler, and others. The idea in all these was that a quantity of water might be kept circulating between two tanks, one above, and one below; being raised to the upper one by means of pumps driven by a water-wheel which derived its motion from the selfsame water in falling the same distance, there being a balance to the good in the form of extra work to be done by the wheel.

A third class of proposals suggests the application of capillary action to raise the water instead of employing pumps, one of the earliest being that of a Professor of of Philosophy in Glasgow about 200 years ago. In this case and others the drawings show (in anticipation) the water thus raised flowing out at the top in a good substantial stream, as, for instance, in the scheme of Branca about the date of the Professor's production.

The fourth and last class, which partook more of a philosophic nature, proposed to employ magnets, the attraction of which is to be effective in one position, and masked in another. There are many proposed ways of effecting this, all equally futile, although one contrived by a shoemaker of Linlithgow actually deceived for a time Sir David Brewster, who communicated an account of it to the *Annales de Chimie*. In the simplest a ball is to fall through a certain distance, so as to come into a position where it can be raised up an inclined plane by magnetic attraction. The first part is carried out in strict

[1] Abstract of a Lecture delivered by Prof. Hele Shaw, University College, on December 21, 1887, in St. George's Hall, Liverpool.

accordance with the programme, but the ball refuses to go through the second part without coercion.

Now most of these schemes had a very definite object in view, which was to obtain motive power, and not at all the innocent philosophic notion of delighting future ages by the sight of a machine which, like the sacred flame Mark Twain tells of, had been going for so many centuries; in short, it was not to benefit posterity but themselves that perpetual motion seekers worked and patented their inventions; and thus the question naturally arises, Did any of their inventions appear to work? Well, they did; and here we may divide these machines into two classes, those which did not succeed, and those which did. The former are in a strong majority, but the latter are important; and I will briefly give an account of one case, perhaps the most celebrated, of the latter. About the year 1712 a great stir was made on the Continent by the appearance of a wonderful machine contrived by a German Pole, by name Jean Ernst Elie-Bessler, who apparently (not perhaps having enough names) had assumed the additional surname Orffyreus. This Orffyreus had, it was said, contrived upwards of 300 perpetual motion machines, and at last had got one that worked. Kings, princes, landgraves, not to say professors and learned men, were all convinced of the absolute certainty of the action of the machine, and Baron Fischer writes to the celebrated Dr. Desaguliers as seriously as Prof. s'Gravesande did to Sir Isaac Newton about it as follows, concerning a visit paid to this machine in the castle of Wissenstein, in Cassel:—"The wheel turns with astonishing rapidity. Having tied a cord to the axle, to turn an Archimedean screw to raise water, the wheel then made twenty turns a minute. This I noted several times by my watch, and I always found the same regularity. An attempt to stop it suddenly would raise a man from the ground. Having stopped it in this manner it remained stationary (and here is the greatest proof of a perpetual motion). I commenced the movements very gently to see if it would of itself regain its former rapidity, which I doubted; but to my great astonishment I observed that the rapidity of the wheel augmented little by little until it made two turns, and then it regained its former speed. This experiment, showing the rapidity of the wheel augmented from the very slow movement that I gave it to an extraordinary rapid one, convinces me more than if I had only seen the wheel moving a whole year, which would not have persuaded me that it was perpetual motion, because it might have diminished little by little until it ceased altogether; but to gain speed instead of losing it, and to increase that speed to a certain degree in spite of the resistance of the air and the friction of the axles, I do not see how any one can doubt the truth of this action." The inventor himself wrote various pamphlets—with dedications 60 pages in length in German—entitled, "Das Triumphirende Perpetuum Mobile Orffyreanum," and in Latin, "Triumphans Perpetuum Mobile Orffyreanum." This machine worked hard, raising and lowering stones or water as required, being locked in a room; the people outside could see the work done by means of a rope which passed through an opening in the wall, and this ought to have satisfied them. Still, there were disbelievers, and amongst others we find a M. Crousaz writing as follows:—"First, Orffyreus is a fool; second, it is impossible that a fool can have discovered what such a number of clever people have searched for without success; third, I do not believe in impossibilities; . . . fifth, the servant who ran away from his house for fear of being strangled, has in her possession, in writing, the terrible oath that Orffyreus made her swear; sixth, he only had to have asked in order to have had this girl imprisoned, until he had time to finish this machine; . . . eighth, it is true that there is a machine at his house, to which they give the name of perpetual motion, but that is a small one and cannot be removed." These are serious charges even if not in logical sequence, and before we conclude the history of this invention we will examine a machine which has been made at University College, which has certainly surprising properties, although very simple. It is now locked, for we may say of it what was said of a machine about twenty years ago by the *Boston Journal*:—"It will not, nay cannot, stop without a brake, as it is so fixed by means of balls and arms that the descending side of the wheel is perpetually farther from the centre of motion than the opposition ascending." That is just our machine, which, started, behaves exactly as Baron Fischer describes, and raises a weight or does other work. This machine is so constructed as to enable complete examination to be made, and all possibility of unfair play apparently detected, and yet it is a fraud,[1] as was that of Mr. Orffyreus, which was afterwards exposed.

The conclusion we arrive at is, that it would have been well for a great number of folks if the saying due to Lucretius nearly 2000 years ago, "Ex nihilo nihil fit," [2] had been appreciated and believed in by them. Thus the waste of many lives of fruitless work might have been avoided not only in the past but even in the present day, for it is an astonishing fact that during the last twenty years more than 100 English and French patents for perpetual motion machines have been obtained; in one case a gentleman not very far from Liverpool having spent a very large sum on this profitable subject. The lecturer stated that the other day he had a visit *in propria persona* from an inventor of, and of course believer in, such a machine, and after having for an hour and a half discussed the question with this gentleman as calmly as was possible under the circumstances, he had grounds for feeling that his lecture would be utterly incomplete if he left the subject content with raising a laugh at the whole matter: not so very long ago it was easy enough to do this at the expense of railways and ocean steamers. He would therefore briefly and simply, but he hoped conclusively, state the general nature of the problem of perpetual motion. Firstly, all machines such as we have seen projected for creating power are as impossible as the idea of creating matter. Secondly, many machines have been projected for using sources of energy, such as heat, as proposed by Desaguliers, and many others since, in which known sources of power were to be rendered available. Such machines continue to work only while the supply of energy lasts, therefore have not perpetual motion. Thirdly, since, just as energy cannot be created, so it cannot be destroyed, but can only take another form, the question arises, Cannot the causes retarding a body's motion be removed and the body go on moving for ever? In order to answer this reasonable question, he proposed for a few moments to search for perpetual motion. He then proceeded to illustrate, by means of a variety of machines, what efforts had been made to reduce frictional resistance. In one case, an inventor working on the principle that in a wheel of half the size the friction was reduced in the same proportion proposed to employ two in this ratio; no doubt with the same idea as the man who, seeing a stove advertised to save half the usual quantity of coal, bought two with the idea of saving it all. Many people thought that, theoretically, friction was entirely removed by means of rolling contact—illustrated by roller and ball-bearings—but it was only because the theory was imperfect, and the true nature of rolling not understood; and, by means of lantern illustrations, the action of rolling surfaces was experimentally examined. The irresistible conclusion must be arrived at that friction is as universal in its action

[1] Being driven by concealed cords passing down the hollow legs and actuated by a youth beneath the platform.

[2] Propounded, indeed, in a different form by Democritus 400 years before that.

as gravitation, and to avoid it on the earth is impossible; and with this conclusion vanishes all hope of a perpetual motion machine. If we are inclined to regret this fact, a little reflection on what would occur if friction ceased to act may not be uninstructive, for the whole face of Nature would be at once changed, and much of the dry land, and, even more rapidly, most of our buildings, would disappear beneath the sea. Such inhabitants as remained for a short time alive would not only be unable to provide themselves with fire or warmth, but would find their very clothes falling back to the original fibre from which they were made; and if not destroyed in one of the many possible ways—such as by falling meteors, no longer dissipated by friction through the air, or by falling masses of water, no longer retarded by the atmosphere and descending as rain—would be unable to obtain food, from inability to move themselves by any ordinary method of locomotion, or, what would be equally serious, having once started into motion, from being unable to stop except when they came into collision with other unhappy beings or moving bodies. Before long they, with all heavier substances, would disappear for ever beneath the waters which would now cover the face of a lifeless world.

We turn to the motion of planetary bodies—is that perpetual? At first, everything seems to show that it is. The earth with its mass of 3000 trillion tons turns with a speed which enables a student to go bare-headed a good many miles without catching cold in the act of saluting a Professor, for a long time defied all attempts to detect in it loss of speed; but with the friction of the tides continually at work such loss must take place, and now it is pretty certain from the calculations of Adams, the astronomer, that the earth loses about an hour in 16,000 years, and is coming to rest, though it must be admitted rather leisurely. So, also, the hurrying up of the comets as they go round the sun is possibly accounted for by a retarding action in space which makes it necessary for them to try and make up, as it were, for lost time; and in fact the general arguments in the present day are in favour of what Sir Isaac Newton believed—that the motions of all bodies in space are suffering retardation, and that their velocity is becoming less and will ultimately cease.

Perpetual motion, then, is impossible. By no means. We have duly considered motion of matter in its visible and mechanical form, and if the foregoing remarks are true, then in this form assuredly it is; but there is, as we have seen, the great fact of indestructibility of energy, and the greatest generalization of the present century is that which accounts for the disappearance of energy in the form of mechanical and visible motion by showing that an exactly equal amount appears in the form of molecular and invisible motion. To this all outward motion tends, and friction is the agency by which the change is effected. Down to a certain point the change can be effected in either direction, and the heat-engine converts molecular motion into mechanical, again to be reconverted into molecular motion in all its working parts, as well as in connection with the useful work it does. This stage reached, there is no process known to us by which the cycle can be continued, and the term "degradation," in the sense of having gone down a step, but nevertheless a step which can never be reclaimed, is applied to the tendency of energy to assume molecular form by dissipation over a larger mass of matter, so that its effect is less intense, though equal numerically in amount. To this all Nature tends, and beyond this point we cannot go. Here, at any rate, the motion is perpetual, but it is motion that tends to approach a state unsatisfactory to the instinct of the human mind. Great intellects, such as Rankine and Siemens, have striven to conjecture ways at present unknown to us by which the energy now spreading itself over the vast expanse of space may be gathered again and regenerated, so that we may look forward not to the lowest but to the highest form of motion as that which, passing through all its cycles, shall last for ever.

THE CHAIR OF DARWINISM IN PARIS.

ONE of the most interesting evidences of the differing results of municipal organization in foreign countries, as compared with those resulting from such organization in our own, is the news that the Municipal Council of Paris intends to found (in connection with the Sorbonne, or the Jardin des Plantes, or the Collège de France, we do not know which) a Chair of Philosophical Zoology, with a special view to the propagation of the doctrine of evolution as elaborated by Darwin. It appears that the official naturalists in France—those holding the leading professorships and museum appointments—have not hitherto been very friendly to Darwinian doctrine. The Municipal Council of Paris has recognized the fact that there is an undesirable hostility to Darwin's views amongst the official group, and actually proposes to remedy the evil results of this hostility by establishing a new Chair, destined to give fair play and a full hearing to the new philosophy. It is as though the Corporation of London should propose to build and endow a laboratory of physiological experiment or of bacteriology. The imagination recoils before the task of picturing Mr. Alderman Greenfat expounding to his colleagues the importance to the community of scientific research, and carrying with him a large majority in favour of a scientific enterprise hitherto neglected and even penalized by middle-class authority.

There is very little doubt as to who is the fittest man in France at this moment to hold such a Chair as that which is now to be created. M. Giard, for many years Professor of Zoology at Lille, and only this year called to a similar Chair in Paris, has not only been the first in France to teach from an official position the doctrine of evolution in zoology, but has made many most valuable researches himself, and has created a school amongst whom are the ablest of the younger French zoologists. Every embryologist knows the works not only of Alfred Giard, but those of his pupils Barrois, Halley, Monnet, and others. Alfred Giard had to submit to some painful remonstrances, and to imperil his official career as a Professor of Zoology in France, when he determined to break with the traditions of his eminent master, Henri de Lacaze Duthiers, and to boldly accept Darwinism and the methods of the modern English and German school. It is therefore only right that his name should be the first to be considered in relation to the new Chair in Paris, and we have no hesitation in saying that, should he be appointed, a man will have been secured as the first occupant of a difficult position whose qualifications render it certain that he will not only do credit to himself, but will justify, by his successful teaching, the enlightened, patriotic, and high-minded initiative of the Municipality of Paris.

E. R. L.

NOTES.

ON the 3rd of this month there passed away a Scottish parish minister, who though not himself a scientific man has come in contact with three successive generations of men of science whom the love of travel or of geology has led to the picturesque island of Skye. The Rev. Dr. Donald Mackinnon was the third of his family who have been ministers of the parish of Strath. His grandfather was appointed to the incumbency in 1777, and held it for forty-nine years. His father took the office in 1826, and held it for thirty years, until he himself succeeded to it in 1856. The parish has thus been presided over by the same family for the long period of 110 years. Unfortunately none of

the numerous family of the deceased clergyman have entered the Church, so that the interesting ecclesiastical connection of the family with the parish now comes to an end. Dr. Mackinnon was a noble type of the true old Highland gentleman, dignified, courteous, kindly, and always the same, whether conversing with crofter or countess. He was delighted to tell his reminiscences of the old geologists. It was his uncle who put into visible expression by his famous but unspeakable "device of the pots" (as Barbour has it) the universal indignation of Skye at the account of the island and its inhabitants given by the geologist Macculloch, in his book on the Highlands and Western Islands. It was in his father's house that Sedgwick and Murchison were entertained when they passed through the north-west Highlands in 1827, and he had some amusing stories about the impression made on himself and his brothers by the doings of these two great brethren of the hammer. In later years geologists and other students of science, as well as artists and distinguished men of many kinds, have enjoyed the hospitality of his home at Kilbride under the shadow of the great mountain, and in sight of the gleaming Atlantic. Only a few months ago he had an opportunity of renewing his early love for mineralogy and geology, and while riding on his favourite quiet cob, looking after his farm-servants as they harvested between the showers of a Skye September, he would stop now and again to point out geological features that had been familiar and interesting to him from boyhood. He belonged to a type of Scottish clergyman that is slowly disappearing, and carries with him the affectionate regrets of everyone who was privileged to enjoy his friendship.

The Annual General Meeting of the Royal Meteorological Society will be held at 25 Great George Street, Westminster, on Wednesday, the 18th instant, at 8 p.m., when the Report of the Council will be read, the election of officers and Council for the ensuing year will take place, and Mr. W. Ellis, the President, will deliver his address.

On Tuesday next (January 17), Mr. George J. Romanes will begin at the Royal Institution a course of ten lectures, being the first part of a course on "Before and After Darwin;" Mr. Hubert Herkomer will on Thursday (January 19), begin a course of three lectures on (1) "The Walker School," (2) "My Visits to America," and (3) "Art Education"; and Lord Rayleigh will on Saturday (January 21) begin a course of seven lectures on "Experimental Optics." The Friday evening meetings will begin on January 20, when Lord Rayleigh will give a discourse on "Diffraction of Sound."

The following are the arrangements for the Penny Science Lectures at the Royal Victoria Hall for the present month:—January 10, "The Great Sea-Serpent," by Arthur Stradling; January 17, "Caves and Cave-Men," by F. W. Rudler; January 24, "The Oldest Monuments in Brittany and Britain," by Prof. Bonney, F.R.S.; January 31, "Speech made Visible, or Picture-Writing as it was, and as it is now," by Prof. Ramsay.

Lectures will be delivered in Gresham College, Basinghall Street, E.C., on January 17, 18, 19, and 20, at 6 p.m., by Dr. E. Symes Thompson, on "Sleep, Sleeplessness, and Pain."

In reference to the review in these columns last week (p. 218) of the second series of collected papers on Indo-China, we observe from the last Annual Report of the Council of the Straits Branch, Royal Asiatic Society, that there is at present no intention of proceeding further with the publication of selected papers on the East Indian Archipelago. The Council, however, expresses a hope that, at some future time, an effort will be made by the Society to translate and publish selected papers which have appeared in the Journals of Societies in Holland and Java, written by learned Dutch Orientalists. The Report adds that the new map of the peninsula, to which we have several times referred, was finished in 1886, but before it could be sent to England the Siamese Government gave further geographical information concerning the northern part of the peninsula, and the map will not be published till this new information is incorporated in it.

In the November Bulletin of Miscellaneous Information, issued from the Royal Gardens, Kew, attention was drawn to the subject of fruit-growing in British colonies, and an admirable report on the fruits of Canada was given. The treatment of the subject is continued in the January Bulletin, which contains full reports sent by the Governments of Victoria, South Australia, Western Australia, Tasmania, New Zealand, Cape Colony, and Mauritius. Prominence is given to the quantity of fruit actually available for export in each colony. To this the writers add the months during which the fruit is in season, and the prices usually paid for it locally. It was intended to publish the reports from the Australian colonies, Tasmania, New Zealand, and the Cape of Good Hope in one series, so as to present a general review of the fruit industries of the Southern Hemisphere; and this was to have been followed by reports dealing exclusively with the fruits of tropical colonies. So far, however, reports from New South Wales and Queensland have not been received.

An interesting paper, by Mr. Daniel Morris, on the use of certain plants as alexipharmics, or snake-bite antidotes, has just been issued. Mr. Morris explains that his enumeration of the plants reputed to possess alexipharmic properties is offered without any expression of opinion as to their value. It is intended chiefly as an attempt to bring together for the first time a summary of information about these plants, in order that inquiry may be made to confirm or refute the popular opinion respecting them. "Opportunities," says Mr. Morris, "to test the action of these plants on a person actually bitten by a well-known poisonous snake are seldom offered to a competent investigator. But as material is being brought together which can be carefully tested by chemical and therapeutical investigations, the most prominent of these plants, such as species of *Aristolochia* and *Mikania*, deserve very careful attention."

A valuable paper, by Prof. Marshall Ward, on the tubercular swellings on the roots of *Vicia Faba*, has just been printed in the Philosophical Transactions of the Royal Society.

Messrs. Swan Sonnenschein and Co. will publish in a few days a new work by Mr. Theodore Wood, entitled "The Farmer's Friends and Foes." The book describes in considerable detail the nature and habits of those animals, birds, and insects which exercise a good or evil influence upon the products of British agriculture, and is profusely illustrated.

We have received the "Annuaire," for 1888, of L'Académie Royale des Sciences, des Lettres, et des Beaux-Arts de Belgique. It contains full information as to the organization, rules, and work of the Academy; and there are several rather elaborate memoirs of late members. Each of these memoirs is accompanied by a carefully-engraved portrait.

Capt. M. Rykatschew, the Assistant Director of the Central Physical Observatory at St. Petersburg, has published in the *Repertorium für Meteorologie* (Bd. xi. No. 2) a discussion of the winds and pressure of the Caspian Sea. The title is misleading, as the observations are made on land, ten stations being on the shores of the Caspian Sea, and nine in neighbouring districts. And the mean winds are deduced by Lambert's formula, which deals with the number of observations without reference to the force of the wind. Nevertheless the work is a valuable and elaborate discussion, based on trustworthy observations extending from three to forty-four years.

The mean wind-frequency and pressure are given for every month, for seasons, and for the year, and charts are drawn for the seasons and for the year. The work is a continuation of previous similar discussions of the winds of the Baltic, the White and Black Seas, and the Sea of Azov.

IN the *Archives des Sciences Physiques et Naturelles* for December 15 last, M. P. Plantamour publishes the results of observations of the periodic movements of the ground from October 1, 1886, to September 30, 1887, as shown by spirit-levels fixed in the exterior and central partition walls of his house at Sécheron, near Geneva. The oscillations are illustrated by curves, from which it is seen that the movements exhibited by the two levels are not always parallel, but vary in a regular manner, and that both curves follow the variations of temperature throughout the year. Experiments have been carried on for nine years, but a longer series is necessary to arrive at definite conclusions.

M. A. F. SUNDELL publishes in vol. xvi. of the Proceedings of the Scientific Society of Finland, the results of comparisons of the standard barometers at the principal Observatories of Europe, with the view of showing what corrections are to be applied to reduce the readings of different countries to absolute uniformity. The comparison shows the existence of considerable differences between the various standards. But as the experiments were made with an instrument which was filled with mercury at each comparison and afterwards emptied, it is a question whether the results obtained may be considered perfectly trustworthy.

A NEW compound of arsenic, containing that somewhat remarkable substance, hexiodide of sulphur, has recently been prepared by Dr. Schneider, of Berlin (*Journ. für prakt. Chemie*, No. 22). Hexiodide of sulphur, SI_6, was prepared some time ago by Landolt by evaporation of a solution of iodine and sulphur in carbon bisulphide at a low temperature: it forms pyramidal crystals, shown by Von Rath to belong to the rhombic system, and, curiously, is isomorphous with iodine itself. It is a compound of considerable theoretical interest, inasmuch as it is the only known instance in which the supposed six combining bonds or affinities of sulphur are satisfied by monad atoms. One would naturally imagine that such a compound would be eminently saturated, and it has never hitherto been known to effect any further combinations; but Dr. Schneider now shows that it is capable of forming a crystalline double compound with arsenious iodide, of the composition $2AsI_3 . SI_6$. This new compound was first incidentally obtained during a lengthy research upon the relations between arsenious sulphide and iodine, and its discovery forms another example of the happy manner in which important results are often most unexpectedly attained by following the by-paths which so frequently lead off from the high-way of systematic research. It may, however, be synthetically prepared by gently warming a mixture of SI_6 and AsI_3 in the proportion of one molecule of the former to two of the latter: the two substances melt together to a deep-brown liquid, which, on cooling, solidifies to a dark gray crystalline mass. The crystals are homogeneous, tolerably hard and brittle, yielding a reddish-brown powder on pulverization; they cannot be preserved in the air, as they lose all their iodine in twenty-four hours, but in sealed tubes may be kept any length of time. The double compound itself, however, is nothing near so interesting as the important theoretical questions which it suggests. We may well ask, Is it possible that the atoms of sulphur are still endowed with a certain amount of combining energy after their six "affinities" are satisfied? or do the iodine atoms act in this case in one of their higher capacities?

AT the last meeting of the Geographical Society of St. Petersburg, M. Kuesenoff gave an account of an interesting nomad tribe in the Ural Mountains, calling themselves Vagueles. In the winter they dwell in wooden huts, and in the summer wander among the mountains, living in tents. At the former season their clothing consists of deerskin, and at the latter of linen garments. They worship the sun and some of the stars, and have a superstitious dread of certain forests, which they deem sacred. Women hold a very inferior position, being treated as slaves. During the last few years contact with more civilized tribes has had a good influence on the Vagueles, and some of them have begun to settle down as tillers of the soil. The tribe is said to be of Finnish origin.

ON December 10, about 6 p.m., a meteor was seen at Hönefos, in Norway. It went in a north-easterly direction, emitting a brilliant bluish-white light, and lasted a few seconds.

ON December 18, about 8 p.m., a magnificent meteor was seen in several parts of the province of Stockholm, going in a direction north-west to south-east. It shone with a bluish light. It left a broad trail in the sky, and eventually burst into tiny fragments, but without any report.

WHAT is believed to be a meteorite has just been dug out of the ferry harbour of Nökjobing, in Denmark. The stone, which weighs about half a ton, was found in soft mud, and no other stones were near it. It is very dark in colour, contains iron, and is of unusual weight for its size, the work of moving it being very laborious. It has now been blasted to pieces, which will be examined scientifically.

LAST year a Phanerogam hitherto never met with in Scandinavia (*Juncus tenuis*, Willd.) was found near Vexio, in Central Sweden. In Europe this plant is found only in a few localities in Germany, Holland, and Scotland.

DURING last autumn, in October and November, ornithologists in the province of Tromsö, in the extreme north of Norway, were interested by the sudden appearance of large flocks of the so called "Nut-crow" (*Nucifraga caryocatactes*), a bird hitherto never seen in Northern Norway, and which is scarce even in the southern part of the country. Several specimens were shot and forwarded to the Tromsö Museum. It is surmised that the birds were driven thus far north, during migration, by stormy weather.

OWING to unfavourable weather, the cultivation of oysters on the coast of Norway was not so successful last year as in previous years.

LAST autumn an attempt was made to bring live cod from Iceland to Norway on board smacks, and 6000 fish were brought over to Bergen successfully. Here, however, many of them died, on account of the basin in which they were kept until the sale could be effected being too small. This year fresh attempts will be made.

THE temptation of French architects seems to be to attend to the decorative rather than the useful parts of the buildings they design. The architect who designed the new Medical School in Paris took so little pains about the distribution of the water-pipes, that in very cold weather the laboratories (chemistry, physiology, bacteriology, experimental pathology, &c.) are wholly deprived of water. Last week the water in all the pipes was frozen, so that not a drop of water was available in a single laboratory. Of course, everyone connected with the school complains that work under such conditions is nearly impossible.

THE new Sorbonne will be a handsome building, but, unfortunately, the work is soon to be stopped owing to lack of money. The ornamental part of the building is finished, but the useful part has not yet been begun.

THE *Ceylon Observer*, writing on the great trigonometrical survey of that island, states that its connection with the con-

tinent of India by a network of triangles is now an accomplished fact, Mr. More, District Surveyor, having in November last finished his series of observations with the large theodolite. Nothing now remains but to reduce the observations, a work which it is anticipated will take about six months. Mr. More had enormous difficulties to overcome in his survey. The north of the island is so much covered with forests that he was compelled to erect lofty stages for his theodolite, at a height of from 40 to 70 feet above the ground; and the observed signals were in many cases 140 feet from the earth. All these stages had to be made on the spot, the appliances at hand being of the poorest description, and it was with the greatest difficulty that the structures thus made were kept at the necessary rigidity. The climate is so uncertain that the surveyors often watched for days without seeing a flash from the heliostat, and at other times every member of the working parties was prostrated by fever. As the observers approached the coast, stone towers were put up instead of timber stages, and these towers will serve not only as permanent survey stations, but as landmarks for those navigating the neighbouring waters. In all, eleven stone towers were erected, and very many wooden stages. Ceylon, by the completion of this trigonometrical survey, is now free from the reproach which it has lain under since the Indian surveyors finished their portion of the work. There is now a complete chain of triangles from Asiatic Russia to the south of Ceylon. The *Observer* adds that it is curious to note that exactly one hundred years ago (1787) a complete triangular connection was formed between Great Britain and France across the Channel under the superintendence of General Roy, R.E.

THE additions to the Zoological Society's Gardens during the past week include a Burrowing Owl (*Speotybo cunicularia*) from South America, presented by the Rev. Basil Wilberforce; a Vulpine Phalanger (*Phalangista vulpina* ♀) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

O'GYALLA SPECTROSCOPIC CATALOGUE.—The systematic survey with the spectroscope, undertaken for the northern heavens several years ago, by Prof. Vogel and Dr. Dunér, the former examining the region from Decl. 1° S. to Decl. 40° N., and the latter that from Decl. 40° N. up to the Pole, has been now carried some considerable distance into the southern hemisphere by Dr. N. de Konkoly and his assistant, Dr. Kövesligethy; and the second part of the eighth volume of the O'Gyalla observations, which has recently appeared, contains a spectroscopic catalogue of the stars down to mag. 7·5, lying between Decl. 15° S. and the equator. The work was commenced in August 1883, and was completed in August 1886, 2797 spectra having been observed on ninety nights. A number of these were observed on more than one night, so that the resulting catalogue contains only 2022 stars. Vogel's arrangement of types was followed, so that the present catalogue is on the same lines as those of Vogel and Dunér. The annexed table gives the number of stars ranged under each type.

I.*a.*	I.*b.*	I *b*?	I.*c*?	II *a.*	II.*b.*	III.*a*	III.*b.*

Continuous.	Monochromatic.	?
41	3	14

The three monochromatic spectra indicate the presence of minute planetary nebulæ. There was only one star spectrum suspected of showing a bright line, a star of mag. 6·5 about 50′ n of ζ Orionis. This latter star, together with β, δ, and ϵ of the same constellation, Dr. Konkoly finds to be variable as to its spectrum. It is to be hoped that the details of the observations upon which so important a statement is based will be published. And it is also to be desired that the work which has been carried so far may now be taken up by some southern observer, and the remaining portion of the heavens surveyed. It is to such works as the present, and the similar labours of Vogel and Dunér, that we must look for evidence of such physical changes amongst the stars as Dr. Konkoly would seem to predicate of the principal stars of Orion.

ASTRONOMICAL PRIZES OF THE PARIS ACADEMY OF SCIENCES.—The Lalande Prize of the Academy has been decreed to M. Dunér for his micrometric measures of double stars, and for his researches on spectra of the third type. M. Périgaud, of the Observatory of Paris, receives the Valz Prize for his important astronomical labours. Amongst those specially mentioned are his determinations of the division errors of four of the circles, and of the absolute flexure of the two principal meridian instruments of the Paris Observatory. The Janssen Prize for important progress in physical astronomy—in the recent sense of the term—awarded this year for the first time, was most appropriately assigned to the late Prof. Kirchhoff. Amongst the general prizes of the Academy should be noted the Arago Medal decreed to M. Bischoffsheim for his great and generous aid to science, and especially for his magnificent foundation of the Nice Observatory. This prize also is now given for the first time. The La Caze Physical Prize is given to MM. Paul and Prosper Henry, chiefly for their great achievements in astronomical photography.

The subject for the Damoiseau Prize for 1888 is proposed in the following question: To perfect the theory of inequalities of long period caused by the planets in the movement of the moon; to see if they exist sensibly beyond those already known.

NEW OBSERVATORY IN VIENNA.—The observatory of Herr M. von Kuffner, the erection of which was commenced in the summer of 1884, has been practically completed. The building is cruciform in shape, and is 82 feet from east to west, and 61 from north to south. The meridian instrument is by Repsold, and has an aperture of 4·9 inches, and a focal length of 5 feet; the eye-piece and object-glass are interchangeable; the circle is 21·6 inches in diameter, and is divided to 2′ and read by four microscopes. The principal equatorial is by the same maker, and has an aperture of 10·6 inches, and focal length of 12 feet 6 inches, with a finder of 2·6 inches aperture, and 26 inches focal length. The co-ordinates of the observatory are provisionally given as long. = 1h. 5m. 11·1s. east of Greenwich, and lat. = 48° 12′ 47″·2 N.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1888 *JANUARY* 15–21.

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on January 15

Sun rises, 8h. 2m.; souths, 12h. 9m. 34·3s.; sets, 16h. 17m.: right asc. on meridian, 19h. 47·1m.; decl. 21° 10′ S. Sidereal Time at Sunset, 23h. 55m.

Moon (at First Quarter on January 21, 5h.) rises, 9h. 18m.; souths, 14h. 1m.; sets, 18h. 51m.: right asc. on meridian, 21h. 39·3m.; decl. 15° 14′ S.

DUNÉR ON STARS WITH SPECTRA OF CLASS III.[1]

II.

A SERIES of observations such as ours ought to add at least a little to our knowledge of the development by which the spectra of stars pass from the second class to one of the two sections of the third, especially if these observations are combined with those made of the stars of the two first classes generally, and of our sun in particular; we might even draw conclusions as to the successive development of stars after they have already reached this class. He who sees trees in a forest in different stages of development, some old, some young, some decaying, can at once form an idea of the different stages undergone by each: it is just the same with the observer of the different classes of stellar spectra.

The spectra of the first class are characterized by the almost total absence of all metallic lines excepting those of hydrogen. In spite of that, we cannot doubt for a moment the presence of metallic gases in their atmospheres, for even in the spectrum of Vega we can faintly distinguish the principal rays of sodium, magnesium, and iron. But these gases are probably at such a high temperature that their power of absorption is very slight. But as the star cools and the spectrum approaches the second class, the metallic lines become stronger and more numerous, whilst, strange to say, the lines of hydrogen diminish. Thus the spectrum becomes more and more like that of our sun in its actual state, and at length, as the metallic lines increase, it resembles that of Arcturus.

Up to this stage of development it is unnecessary to consider the two divisions of the third class separately, but after this it becomes indispensable.

In those spectra which at length become III.*a*, the change seems to operate as follows. On account, probably, of the progressive cooling, the metallic lines, especially those of iron, magnesium, calcium, and sodium, become larger, and, besides these, numerous weak narrow lines are seen grouped together, generally in the neighbourhood of the stronger lines. At this stage it is often difficult, if not impossible, to decide, with spectroscopes of small dispersion, whether one sees broad lines or real bands (or flutings). This happens in the spectrum of Aldebaran. The faint lines go on accumulating, until they cannot be separated from one another and occupy broader spaces, and now the spectrum is easily seen to belong to Class III.*a*. At first the bands in the red and orange are the only ones distinctly visible; but later the bands in the green-blue and in the blue become very strong and broad.

While the development of the stars III.*a* was very well known before my researches, former observers have known no star with a spectrum intermediate between II.*a* and III.*b*. Thus, M. Pechülé declares the hypothesis of the co-ordination of the III.*a* and III.*b* classes to be inadmissible. On the other hand, he seems disposed to think that the spectra III.*b* represent a phase, perhaps the last before its total extinction, in the development of each star, and that the passage from type III.*a* to III.*b* takes place suddenly or by a catastrophe, during which the bright lines appear ("Expedition Danoise," pp. 22-25). M. Pechülé seems, however, to consider this hypothesis doubtful, and at length declares that the physical *rôle* of the stars III.*b* is still quite a mystery.

A very simple explanation clears up at least part of this mystery. If the hypothesis which I, in full agreement with M. Vogel, have suggested be correct, the stars intermediate between the second and third classes must necessarily be comparatively rare, considering that this is only a transitory phase of their existence. The general spectroscopic observations of M. Vogel affirm this fact, for amongst the numerous stars examined by him there are only forty-eight whose spectra are denoted by II.*a* ! ! ! II.*a* ! ! or II.*a* ! But as the lines must be very distinctly visible in the spectra of the stars which are on the point of passing from the second class to Class III.*a*, we are obliged to acknowledge that almost all the stars of this category within the zone examined by M. Vogel are among these forty-eight objects. At first sight one might be disposed to seek these stars among those whose spectra are designated by M. Vogel by II.*a* (III.*a*), II.*a*? III.*a*, and III.*a* (II.*a*); but a closer examination shows that although it is not impossible that these spectra may be among these objects, they must be so rare that that is of no essential consequence as regards the question which occupies us.

Amongst these stars there are none which attain the magnitude 4·5, and only fourteen which surpass the magnitude 6·4. All the others are faint objects, and the ambiguous symbols show the difficulty M. Vogel found in recognizing with certainty the details in the spectra, and not that he could not decide with certainty to which of the two contiguous classes a spectrum of which he could easily perceive the details belongs. The correctness of this supposition is, however, proved by the circumstance that certain spectra are designated by III.*a* (III.*b*), or III.*a*? III.*b*. And none will believe that M. Vogel meant to imply that these spectra were in the act of passing from one section of the third class to the other. Besides, one of these stars is R Serpentis, whose spectrum when the star is at the maximum is one of the most strongly marked of III.*a*, according to M. Vogel's earlier researches, and according to mine. But in his general spectroscopic review M. Vogel examined it when its magnitude was only 9·0, and therefore it was easy to doubt, on account of the excessive width of the bands, whether the spectrum might not be III.*b* instead of III.*a*.

Consequently, although I think I am right in admitting that most of these stars belong to the pure type II.*a* or III.*a*, I will nevertheless suppose that a third of them really have spectra intermediate between II.*a* and III.*a*. Their number in M. Vogel's catalogue is 120, and the third is 40, so we should have therefore between the Pole and $-25°$ declination 160 spectra intermediate between II.*a* and III.*a*. I found also by special observations that among the spectra designated by II.*a* ! ! ! II.*a* ! ! and II.*a* ! a fourth part really belong to the intermediate type. Thus there would be in all 200 such spectra, a number evidently much too great. Then, the spectra III.*b* being about fifty times rarer, we should have at most four spectra intermediate between II.*a* and III.*b*, and if only stars of a higher magnitude than 6·0 are reckoned, there would scarcely be one.

But, if we consider the differences between the spectra III.*a* and III.*b*, we shall find that in reality we can scarcely expect to find any spectrum intermediate between II.*a* and III.*b*. As we have seen above, the spectra III.*a* are formed by the exaggeration of the essential characteristics of the spectra II.*a*. There must then be a phase, especially if the star is not very bright, in which one cannot decide to which of the two classes the spectrum belongs. Thus in the spectra III.*b* there are undoubtedly well-marked Fraunhöfer lines—for instance, D, and the narrow band 8, which is probably nothing but the collection of strong lines in the neighbourhood of E, and the very narrow band 5 ($\lambda = 576\mu$) which is almost like a broad line; but all these details are only secondary. The essential characteristics are the three nebulous, very broad flutings, which owe their origin to some carbon compound. If these bands are visible, the spectrum is called III.*b*; if they are not, it is called II.*a*. The only forms intermediate between the spectra of the type of Aldebaran and the normal

[1] Continued from p. 236.

type III.*b* are those in which the bands are more or less faint, or even scarcely perceptible. In fact, I have proved not only that there are spectra in which the principal bands, and especially band 6, are weak on account of the brightness of the stars, but I have found a spectrum which is scarcely a spectrum III.*b* yet, but in which the characteristics of this class are undoubtedly present.

This star is DM. + 38° 3957 = 541 Birm. In its spectrum (Planché, Fig. 6) I have seen a rather broad and well-marked band, whose approximate wave-length is 519μ, and the spectrum terminates abruptly at 475μ. These wave-lengths are, within the limits of probable errors, the same as those of the less refrangible ends of bands 9 and 10 in the spectra III.*b*. Once I thought I perceived a very faint trace of light beyond 475μ, and in the best atmospheric conditions I caught a glimpse of faint traces of the bands 4 and 6. Unfortunately the star is only of the eighth magnitude, so that only few details of its spectrum can be seen with a telescope like ours. Nevertheless, what I did see seems to me of some importance in explaining the development of a spectrum II.*a* into III.*b*.

If this spectrum be compared with those of other stars of the same or even of a lower magnitude, such as 145 Schj. DM. + 34° 56, DM. + 36° 3168, it is at once seen that in the former the principal bands are still in a very low stage of development, and if the bands had only been a little paler nothing unusual would have been seen in the spectrum under ordinary atmospheric conditions. The aspect of this star seems to prove what I said above, that there is, properly speaking, no intermediate state between the spectra II.*a* and III.*b*, but that the passage from one to the other is already accomplished before the first traces have been perceived.

But there is still one more circumstance deserving of attention, which may perhaps lead to the knowledge of other spectra which are still nearer to the critical point; that is, the very strong absorption of the more refrangible rays, which makes the whole spectrum very short, and gives to the star itself its bright orange colour. We know that there are many stars of a deep colour and with short spectra, but otherwise not striking; they ought to be examined from time to time with very powerful microscopes, for amongst these will be found, I believe, the new spectra III.*b*.

There are other spectra, which, although they undoubtedly belong to Class III.*b*, have not, it appears, reached their full development. The least faint of these stars is that known as 7 Schj. Before my researches, nothing had been published regarding this spectrum except this short remark of D'Arrest, "Irregular spectrum, probably type IV." (*Vierteljahrschrift der Astr. Ges.* ix. Jahrg. p. 255). This spectrum presents the characteristics of III.*b* very pronounced; only band 5 is invisible, and band 6 is so faint that at first sight the spectrum has not the aspect characteristic of well-developed spectra of this class. It is for this reason that D'Arrest would say nothing positive regarding this star. If the spectrum of 541 Birm. represents the first step in the passage of a star to Class III.*b*, this star doubtless represents the second step. Band 6 is the least developed of the three principal ones. Although the spectrum of this star is pretty bright, band 5 is not visible, whilst band 4 is well visible, and is also perceived in the spectrum of 541 Birm.

In the spectrum of 19 Piscium (Fig. 4 on the map), which is one of the most magnificent in other respects, band 6 is still considerably fainter than the other two principal bands, whilst in that of 152 Schj. (Fig. 3) it is quite as pronounced as band 10, and almost as pronounced as band 9. This last spectrum is in an advanced stage of development; but in spite of that, band 4 is not stronger than in the spectrum of 7 Schj., and rather fainter than that of 19 Piscium. The same relation is repeated in other spectra of this class, so that sometimes band 4 is very visible in an otherwise less developed spectrum, but invisible in more strongly marked spectra, and in the spectra of brighter stars of this class there are in the same way very faint bands, 7 and 8. But band 4 is in itself very pale; it is the deep sodium line which makes it remarkable, and the bands 7 and 8 are probably only groups of Fraunhöfer lines.

It is therefore very probable that the more or less easy visibility of these bands is no indication as to the phase of development in which the star is. There is, on the contrary, reason to believe that the strengthening of these lines, and also of the other principal lines of the spectrum (except those of hydrogen, which grow fainter during the passage of a star to Class III.) is a process of relatively small importance which goes on whilst the star still undoubtedly belongs to Class II.*a*; and even when this is accomplished there is still nothing to show whether the star will become III.*a* or III.*b*, unless perhaps in those which tend towards Class III.*a*, the line, or rather group of lines, with wave-length 616, is very well marked, which seems not to take place in the spectra III.*b*. But in the stars which tend towards the latter class the violet rays are already very much absorbed, and the stars are therefore of a deep orange.

If we pass on to consider the ulterior development of the star, it is evident that as it cools further it at length reaches a temperature at which the carbon which must be present in abundance, either in its atmosphere or under some form in its photosphere, can combine with hydrogen or some other element to give the so-called hydrocarbon spectrum. After that, the spectrum appears cut by a broad faint band with the wave-length 516μ, and by another still paler at 473μ, and the parts of the spectrum beyond this are very faint. But gradually these two bands increase in intensity, and at the same time the band 563μ is perceived, at first very faintly, and gradually becoming stronger. At this stage the narrow band 576μ is developed, and finally the three principal bands are nearly of equal intensity, and the spectrum shows all the characteristic details. It would be useless to attempt to discuss the moment at which the secondary bands in the red and orange make their appearance, as no facts on the subject are known.

It is doubtless very remarkable that in the spectra III.*b* no trace of the carbon band with the wave-length 618·7μ is seen, which is so brilliant in Plücker's tubes containing hydrocarbon. This is, however, in perfect analogy with what is seen in the spectra of comets, which owe their appearance to the same carbon compound as the stellar spectra III.*b*, and there are analogies also for the other bands. Thus the band 563μ is often very weak even in the bright comets, and the band in the green is always the strongest both in comets and stars. The band in the blue is sometimes pretty faint in cometary spectra, whilst in the stars it is only a little fainter than the band in the green; but we must remember that it is situated in a very faint part in the spectra of the stars. It is therefore very possible that a little dimness should render the remaining light entirely imperceptible. In this perhaps there is no diversity between comets and these stars. The violet bands are very faint in Plücker's tubes, but strong in the flame of alcohol. A trace of them has been seen in the spectra of the brightest comets. In very brilliant, not too red stars III.*b*, there is also a violet zone, terminating at the wave-length 430μ, of which there is a band at the position of the first and the second of these bands in the spectra of these stars.

We will now pass on to consider the changes which take place in stars of Class III. after their spectra have completely developed. As the cooling goes on, they necessarily grow dimmer and dimmer, and at length become extinct. Either the bands in their spectra must increase in width until at last the shining intervals disappear, or else, the bands keeping their same width, the whole spectrum grows fainter. Certainly we see that there are stars whose bands are enormously broad, but none the breadth of whose bands surpasses that of the bright zones.

I think, therefore, we can hardly accept the first hypothesis, but there are reasons which give very valuable support to the second. We know that the weakness of the light in the solar spots is, in the first place, caused by a general obscuration of the spectrum, and that the enlargement of the Fraunhöfer lines has very little to do with it. Besides, I have examined, on different occasions, between the maximum and the minimum, the spectra of several variable stars of Class III., and found that there was no widening of the bands sufficient to explain the weakening of the stars. There is no doubt a remarkable analogy between the spectra of the sunspots and those of the stars of Class III., and one which we have no cause to be surprised at. For, on account of the relatively low temperature of these stars, it is very probable that their surfaces are in great part covered with formations similar to our sunspots, and the absorption-bands found in their spectra are no argument against this analogy. They prove only that chemical compounds may be formed and maintained in the atmospheres of these stars, which is not possible in our sun, not even in the masses of relatively low temperature of which the spots consist.

Before laying down my pen I must remark that the induction by which I arrived at these conclusions does not prove that the spectrum of each star commences with Class I. and finishes with

Class III. The development might just as well be in inverse order, though we have important reasons for believing it is not so.

The astronomy of the future must decide between these two alternatives. My object in undertaking this work was to facilitate this decision by giving as exact descriptions as possible of the spectra presented by the different stars of Class III. in the year 1880.

THE ART OF COMPUTATION FOR THE PURPOSES OF SCIENCE.[1]

II.

SOME few problems in astronomy and certain theories in pure mathematics require more than seven figures to be calculated. In these cases a large arithmometer is generally the most convenient. Ten-figure tables of logarithms may be obtained second-hand; or the required logarithms must be calculated.

The tables of Vlacq, re-edited by Vega in 1749, 1794, and 1797 are somewhat difficult to obtain and cumbrous to use. The logarithms of numbers up to 101,000 are given to ten figures with first and second differences. Thus to find log 10 542 482 375, from the table directly

$$
\begin{array}{llll}
\log 10\,542 = & \cdot0229\,230\,119 & \Delta_1 = & 411\,946 \\
 & \quad\;\; 198\,712\,3 & & 482\,375 \\
 & \qquad\qquad 5 & & \\
 & & & 1\,647\,784 \\
\text{log required} & \cdot0229\,428\,836\,3 & & 329\,557\,+ \\
 & & & 8\,239\,+ \\
\text{The true log of } 10\,542\,482\,375 \text{ is} & & & 1\,236\,+ \\
\quad\cdot022\,942\,883\,626\,562. & & & 288\,+ \\
 & & & 20\,- \\
 & & & 198\,712\,3\,1 \text{ subtracted.}
\end{array}
$$

$$\Delta_2 = 40$$

$$\frac{\cdot48(\cdot48 - 1)(-40)}{2} = 4\cdot992.$$

In default of Vega, or if more places are required, the logarithm must be calculated, and this is by no means such a serious affair as one is led to think by the ordinary books on algebra. I am much indebted in what follows to the article by Mr. J. W. L. Glaisher on logarithms in the new edition of the "Encyclopædia Britannica," to which I refer my readers for further particulars in theory, restricting myself to practical details.

The easiest way to calculate a table of logarithms absolutely *de novo* would be by the method of differences, with some mechanical assistance, such as the difference-engine of Babbage or of Scheutz. It seems unlikely that larger tables will be calculated than those already in existence, since the cost increases with great rapidity. Mr. Sang has, however, recently calculated independently the logarithms of numbers from 100000 to 200000, where the ordinary tables are weakest.

Briggs used at least two methods for the calculation of logarithms which depended upon the extraction of a succession of roots. For instance, by taking the square root of 10 fifty-four times he found log $1\cdot(0)^{15}1\ 278\ 191\ 493$ to be $\cdot(0)^{15}0\ 555\ 111\ 512$. Whence assuming that very small numbers vary as their logarithms, log $1\cdot(0)^{15}1 = 555\ 111\ 512/1\ 278\ 191\ 493$, or log $1\cdot(0)^{15}1 = 0\cdot43\ 429\ 448 = \text{M}$, the modulus. And if x be small, log $1\cdot(0)^{15}x = x \times 0\cdot43\ 429\ 448$. To find log 2 he extracted the square root of the tenth power, 1024/1000 forty-seven times, and found $1\cdot(0)^{15}1\ 685\ 160\ 570$, which multiplied by M gave $\cdot(0)^{15}0\ 731\ 855\ 936$. This multiplied by 2^{47} gave log $1\cdot024$; adding 3 and dividing by 10 gives log 2. Another more simple method was to find a series of geometrical means between two numbers, such as 10 and 1, the logarithms of which are known. After taking 22 of these roots, log 5 is found to be 0·69897.

It was soon found that logarithms could be more easily calculated by the summation of various series, and many great mathematicians, such as Newton, Gregory, Halley, Cotes, exercised their ingenuity in discovering those most suitable for the purpose.

Though for practical purposes the use of series has been almost superseded, three very simple ones are still occasionally useful:—

$$\log(1 \pm x) = \text{M}\left(\pm x - \frac{x^2}{2} \pm \frac{x^3}{3} - \frac{x^4}{4} \pm \frac{x^5}{5} - \right)$$

which converges rapidly if x be small. M is a number depending upon the system of logarithms adopted, and constant for each system. If M be 1, the system is called the Naperian, or natural one; and if M = 0·434 &c., the system is the common one. Unless otherwise stated M will be assumed to be 1, or the logarithms will be natural ones.

Thus to calculate $\log 1\cdot1 = 1 + \frac{1}{10}$, omitting M:—

$$\log 1\cdot1 = \frac{1}{10} - \frac{1}{200} + \frac{1}{3000} - \frac{1}{40000} + \frac{1}{500000} -, \text{\&c.},$$
$$= 0\cdot1003\ 3534 - 0\cdot0050\ 2517 = 0\cdot0953\ 1017.$$

Suppose x be small, $\log(1 \pm x) = \pm \text{M}x$ nearly. Thus if $\log 1\cdot(0)^{10}9$ be required to twenty decimals, it is

$$\cdot(0)^{10}9 - \frac{1}{2}(\cdot9 \times 10^{-10})^2,$$

or the error caused by omitting this and all subsequent terms is only 4 in the twenty-first decimal place. Using common logarithms the multiplication by M reduces the error by one-half. This result is of great importance in calculating logarithms by Flower's method, since the factors which have to be dealt with are only half the number of decimal places in the required logarithm.

Writing $\frac{1}{x}$ for x in the above series, we obtain—

$$\log(1 + x) - \log x = \text{M}\left(\frac{1}{x} - \frac{1}{2x^2} + \frac{1}{3x^3} - \frac{1}{4x^4} + \frac{1}{5x^5} - \right)$$

which converges rapidly when x is large. Various artifices may be used to render x large, even when the number the logarithm of which is required is small. Thus, Prof. J. C. Adams has calculated (NATURE, vol. xxxv. p. 381) log 2, log 3, log 5, log 7, $\frac{1}{\text{M}}$ and M to 270 places of decimals.

Another very valuable series is—

$$\log(a \pm x) = \log a \pm 2\text{M}\left\{\frac{x}{2a+x} + \frac{1}{3}\left(\frac{x}{2a+x}\right)^3 + \frac{1}{5}\left(\frac{x}{2a+x}\right)^5 + \text{\&c.}\right\}$$

Thus, supposing log 219 known, to calculate log 2198:—

$$\log 2198 = 7\cdot6916\ 5682\ 2810 + 2\left\{\frac{4}{2194} + \frac{1}{3}\left(\frac{4}{2194}\right)^3 + \text{\&c.}\right\}$$

$$
\begin{array}{ll}
\quad\cdot0036\ 4630\ 8113 & \dfrac{4}{2194} = \cdot0018\ 2315\ 40565 \\
\qquad\qquad\quad 4039 & \\
\log 2198 = 7\cdot6593\ 0313\ 4962 & \dfrac{2}{3}\left(\dfrac{1823}{10^6}\right)^3 = \cdot0^8 4039
\end{array}
$$

Using common logarithms, the third term of the series is $< \frac{1}{27\cdot6}\left(\frac{x}{a}\right)^3$, that is less than 5 in the ninth place when $\frac{x}{a} < \frac{1}{200}$. Hence, with a table giving the logarithms of 100–1000 to eight figures the third term may be neglected, or the required difference is $\pm \frac{2\text{M}x}{2a + x}$, or, writing $\log(a + x) - \log a = y$, $x = \frac{2ay}{2\text{M} - y}$.

The given numbers may also be broken up into factors by the aid of such a table as Burkhard's, which gives the factors of all numbers up to 3,036,000. The logarithms of the factors may then be found from tables and added together. Of all tables for this purpose, that of Wolfram is the most valuable; it gives the natural logarithms to forty-eight places of *all* numbers up to 2200, and of all which are not easily divisible up to 10,009.

The multiplication by M to convert into common logarithms is tedious, and it is frequently better to dispense with it in heavy calculations. If necessary, a table of the first ninety-nine multiples of M should be prepared, and Oughtred's short method of multiplication used.

If any of my readers desire to test themselves and their tables

[1] Continued from p. 239.

by a long but easy calculation, the amount of £1 laid up at 5 per cent. compound interest for a thousand years will be found not to differ very much from £1,546,318,920,731,927,238,982. An answer of this sort is of course of no practical utility whatever, but it brings vividly before us an important point in political economy—the accretion of wealth in the hands of corporations. It was computed that just before the Revolution more than half the soil of France was owned by the Church. Looking at this array of figures, and remembering that since the Church could never alienate its property all surplus income must be regarded as at compound interest, we can only wonder that it was the half and not the whole.

The first table for facilitating the computation of logarithms was one given by Long (Phil. Trans., 1724) of the decimal powers of 10 to nine figures. Thus, to find the number the logarithm of which is

$$·30103 = 10^{·3} \times 10^{·001} \times 10^{·00003} = 1·99526231 \times 1·00230523 \times 1·00006908 = 1·99999997, \text{ or } 2.$$

This method is cumbrous, but it is perhaps one of the most simple for explaining the calculation of logarithms to beginners.

A much more convenient method has been well worked out by M. Namur, but, unfortunately, only his twelve-figure table seems to be still in print. The table contains the logarithms of numbers from 433300 to 434300 to twelve figures, and the numbers corresponding to logarithms from 637780 to 638860. By the aid of certain factors which are tabulated with their complementary logarithms, any number or logarithm can be reduced between these limits.

Thus, to find log π—

	314 159 265 359	× 1·3
	94 247 779 607 7	
	408 407 044 956 7	× 1·063
	24 504 422 698 0	
	1 225 221 134 9	
	434 136 688 799 6	
log from table	637 625 800 474	Δ = 1·000364
	206 4	
	41 3	
	2 4	
	637 626 489 524	
	973 466 735 477	complementary logs of 1·3 and 1·063
	886 056 647 693	
	497 149 872 694	= log π.

The last method I shall mention is generally known by the name of Weddle; it was probably used by Briggs, and published by Flower in 1771. It consists in multiplying the given number by a series of factors of the form $1 \pm \frac{x}{10^n}$ until it is reduced to one. The complement of the sum of the logarithms of the factors is the required logarithm. The logarithms of the factors are easily calculated by the first series; they have been tabulated to about thirty places.

Thus to find log 3550·26:—

355026 × 2	30103	
710052 × 1·3	11394 3	
2130156	3342 4	
9230676 × 1·08	130 1	
738454	3 9	
9969130 × 1·003	44973 7	
29907	55026	complement.
9999037 × 1·00009		

Hence log 3550·26 = 3·55026, or we have a number which is expressed by the same figures as its logarithm.

It is the present fashion, while depreciating our own country men, to extol all Germans in matters connected with education, and especially to award them the palm for patient plodding. It will be some time before a German rivals Prof. Adams, and even then there is a height beyond. Of all monuments of calculation the value of π, or the number of times the circumference is longer than the diameter of a circle, is most astounding. Archimedes found it to be $\frac{22}{7}$, Wolf calculated it to 16 places, Van Ceulen to 35, Machin to 100, Beerens de Haan to 250, Richter to 500. But in 1853 Mr. Shanks threw all these results into the shade, and excited the admiration even of De Morgan by calculating π to 530 places, "throwing aside as an unnoticed chip the 219th power of 9"! Two printers' errors were pointed out by Mr. John Morgan, which Mr. Shanks corrected from his manuscript, and in 1873 gave a new result to 707 places. Hence the value of π is known to within $\frac{1}{3 \times 10^{707}}$, an exactness which is useless from the inability of the human mind to comprehend the figures which express it.

Clerk Maxwell proposed, possibly in irony, to take the wave-length of a certain light as the universal unit of length. Choosing for this purpose about the middle of the violet, a mile would be expressed by 60000 × 63360 = $3·8 \times 10^9$ units nearly. Suppose that Sirius, the brightest star in our firmament, has an annual parallax of $\frac{1}{5}''$, a quantity perceptible, but barely measurable, by our best telescopes, the distance of the sun from Sirius is about 5 × 206,265 × 92,300,000 miles, or $3·5 \times 10^{23}$ units. Assume again that Kant's fanciful conjecture is correct, and that the sun revolves round Sirius in a circle the length of which is expressed by $7 \times 10^{23} \times \pi$ units. Make the still greater assumption that all our measures are correct, and our arithmetic as it ought to be, so that the only possible error would be in the evaluation of π. The greatest possible error according to Mr. Shanks's determination would be $\frac{7 \times 10^{23}}{3 \times 10^{707}}$ or $\frac{1}{4·3 \times 10^{683}}$ of a wave-length of violet light. Whatever metaphysicians may say, I think we have here reached, if not surpassed, the limits of the human understanding.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, January 2.—M. Janssen, President, in the chair.—On an objection made to the employment of electro-magnetic regulators in a system of synchronous timepieces, by M. A. Cornu. This is a reply to M. Wolf's recent communication, in which several objections were urged against the apparatus in question. It is shown (1) that such a regulator does not necessarily tend to stop the system to which it is applied; (2) that in any case the stoppage may be prevented without complication or expense; and (3) that in a public time-distributing service the stoppage should not only not be prevented, but efforts should be made to bring it about whenever the synchronizing system gets out of order. The paper was followed by some further remarks on the part of M. Wolf, who reiterated his objections, and treated M. Cornu's third point as somewhat paradoxical.—Remarks on Père Dechevrens's letter regarding the artificial reproduction of whirlwinds, by M. H. Faye. The author complains that, like other partisans of the prevailing ideas on the subject of tornadoes, typhoons, and cyclones, M. Dechevrens endeavours to suit the facts to the exploded theory of an ascending motion in the artificial reproduction of these aërial phenomena.—On the meteorite which fell at Phû-Long, Cochin China, on September 22, 1887, by M. Daubrée. In supplement to M. Delauney's communication of December 19, the author adds that this meteorite was an oligosiderite of somewhat ordinary type, closely resembling those of Tabor (Bohemia), July 3, 1753; Weston (Connecticut), December 14, 1807; Limerick, September 10, 1813; and Ohaba (Transylvania), October 10, 1817.—Remarks in connection with the presentation of the "Annuaire du Bureau des Longitudes" for 1888, the "Connaissance des Temps" and the "Extrait de la Connaissance des Temps" for 1889, by M. Faye. Amongst the fresh matter added to the "Annuaire" this year are papers by M. Janssen on the age of the stars, by Admiral Mouchez on the progress of stellar photography, and by M. d'Abbadie on his recent expedition to the East in order to determine the elements of terrestrial magnetism in Egypt, Palestine, and Syria.—Observations of Olbers' comet made at the Observatory of Nice (Gautier's 0·38 m. equatorial), by M. Charlois. These observations are for December 25, 26, and 27, after the comet was discovered on December 23, when the nucleus was of the tenth magnitude, surrounded by a bright nebulosity, and with tail from 20′ to 25′ in length.—On the total eclipse of the sun

observed on August 19, 1887, at Petrovsk, Government of Jaroslav, by M. G. M. Stanoiewitch. Owing to the extremely unfavourable atmospheric conditions the observer was unable to carry out any important part of his programme. A chief result of his observations was the conclusion that the gloom prevailing during eclipses is all the deeper the less clouded is the sky and the flatter the ground, especially on the horizon. The sky being on this occasion almost completely overcast, he was able to read the title of a pamphlet printed on a red cover at a distance of 2 metres.—On the variations of temperature of gases and vapours which preserve the same quantity of heat under different tensions, by M. Ch. Antoine. A simple means is proposed for avoiding the laborious calculations required to determine the values Θ and Θ^1 in the formula $y = 25\sqrt[3]{\Theta - \Theta^1}$ deduced from V. Regnault's experiments on atmospheric air.—On the energy needed to create a magnetic field and to magnetize iron, by M. Aimé Witz. The researches here described serve to verify Lamont's statement that the effect produced by a magnetic field on a magnet is greater when the force acts to diminish than it is when the force acts to increase the magnetizing power.—On the rapidity of transformation of metaphosphoric acid, by M. Paul Sabatier. Solutions of metaphosphoric acid are transformed spontaneously with greater or less rapidity. Berzelius and Thomsen suppose that there is at first production of pyrophosphoric acid, which is afterwards changed to orthophosphoric acid. Others, with Graham, think that there is immediate formation of tribasic orthophosphoric acid, and the author's researches tend to show that this is normally the case It is also established that the rapidity of transformation is at each instant proportional to the mass of transformable substance present in the system.—On an alloy of titanium, silicium, and aluminium, by M. Lucien Lévy. Wöhler indicated two alloys of these metals without giving their composition. The author here determines a similar alloy differing in some of its properties from those of Wöhler. He has also determined its composition, as apparently a mixture of two isomorphous bodies crystallized together with formula $TiAl_4$ and $SiAl_4$. The same preparation with zinc or magnesium substituted for aluminium yielded no results.—On some derivatives of cinchonine, by MM. E. Jungfleisch and E. Léger. The authors were able some time ago to announce that the sulphate of cinchonine being heated to 120° C. for forty-eight hours with a mixture in equal parts of sulphuric acid and water, the alkaloid changes to diverse bases, of which they have isolated the six most abundant. Here they explain the process by which they have succeeded in separating the alkalies.—On the presence of diaphragms in the aëriferous ducts of roots, by M. C. Sauvageau. The transverse diaphragms intersecting the aëriferous ducts of vascular plants have hitherto been supposed to be confined to the middle region of the bark of their various members. But the author has now determined their presence also in the root of at least one such aquatic plant, the *Hydrocharis morsus-ranæ*.

Berlin.

Physiological Society, December 16, 1887.—Prof. du Bois Reymond, President, in the chair.—Herr Meyer, from Hamburg, discussed the nature of ventriloquism, and combated the opinion, so widely spread among physiologists, that it consists in speaking while inspiring, and without the cavity of the mouth acting in any way as a resonator; on the contrary, ventriloquists speak while expiring, and do move their mouths. An extended series of laryngoscopic observations on the speaker, who has practised ventriloquism for many years, has shown that in ventriloquizing the vocal opening of the larynx is shortened as it is when producing the falsetto, and that the soft palate is pressed back and that the uvula becomes invisible. Everybody who naturally possesses a high voice can easily learn to ventriloquize. One most important factor in the deception of the listeners is the contrast between the loud, full and metallic tone in which the question is asked and the answer which immediately follows in a high and gentle falsetto. Sibilants and the high I should be as far as possible avoided. The speaker then gave a series of extremely successful examples of ventriloquism, which did not presuppose any particular training, and showed that it is never accompanied by any special action of the abdominal muscles. Prof. Gad has made some experiments on Herr Meyer, and by graphically recording the variations in pressure of the air, has shown that the curve obtained when a certain sentence is spoken in the ordinary way is in all respects identical with the one which is described when the same sentence is spoken ventriloquially. In the latter case the volume of air expired was considerably less than during normal speech; in one particular case it amounted to only 900 c.c., whereas during normal speech the volume expired was 1300 c.c. Dr. Benda expressed his idea that when ventriloquizing the Eustachian tubes are open and the cavity of the tympanum, together with the tympanic membrane, are set into simultaneous vibration. He had not been able to detect any resonance of the tympanic membrane in Herr Meyer; but he believes that this explanation of the curiously veiled tones emitted is not thereby invalidated, since they closely resemble the tones produced by speaking while yawning, in which case the Eustachian tubes are certainly open and the tympanic cavity acts as a resonator.—Dr. Benda gave a further account of his researches on the development of spermatozoa, and referred to several works which have been recently published and do not agree with the results obtained by himself. For his own part he could only confirm his earlier opinions by his later researches. In Marsupials he finds some resemblance to that which holds good in Sauropsida. In general it may be said that the very varying relationships observed in Mammalia between the parent-cell and the spermatozoa-cells which are connected with this may be looked at from one common point of view; it is only necessary to adopt for animals the differentiation of the cells of pollen-grains, observed by botanists, into vegetative or nutritive, and into generative, from which the spermatozoa then arise. These vegetative and generative cells can be made out both in the functioning and not yet active testes of embryos, the cells having extremely varying relations each to the other.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

THURSDAY, JANUARY 19, 1888.

THE TEACHING OF ELEMENTARY CHEMISTRY.

Elementary Chemistry. By M. M. Pattison Muir, M.A., Fellow and Prælector in Chemistry of Gonville and Caius College, and Charles Slater, M.A., M.B., formerly Scholar of St. John's College, Cambridge.

Practical Chemistry: a Course of Laboratory Work. By M. M. Pattison Muir, M.A., and Douglas Carnegie, B.A., Demonstrator of Chemistry, and formerly Scholar of Gonville and Caius College. (Cambridge, at the University Press, 1887.)

DURING the past few years numerous expressions of dissatisfaction have been more or less openly uttered by members of the younger generation of English chemical teachers, and the opinion is gaining ground that instruction in the elements of the science can no longer be imparted entirely on the stereotyped lines of practice devised to suit the requirements of a bygone generation—of a time when a science of chemistry was but beginning to exist, and the conviction had not yet been acquired that the subject *must* ultimately be reckoned as a necessary element of a liberal education. Several of the objectors have advanced their criticisms to the constructive stage, thereby rendering great service to the cause; nevertheless we believe it is the general opinion that, although each contains numerous good points, all the schemes hitherto advanced are in the main failures, and that it is impossible to accept any one as it stands. The senior author of the works now under notice has been one of the most active objectors to the good old-fashioned style of teaching, and has told us in terms somewhat vague and general it is true, but none the less plainly, what we ought to do. Even chemists recognize, however, how comparatively easy it is to preach and yet how difficult to practice, and we have therefore patiently awaited the publication of details to guide us on the tortuous and narrow path to success. These details are now before us in the two books of which the titles are given at the head of this article; "they are intended to be used together," say the authors, and "their object is to teach the elements of chemical science." What will be the verdict of, say, a jury of schoolmasters—by far the most competent judges on such a question—as regards the merits of the scheme put forward by Messrs. Muir, Carnegie and Slater? We venture to predict, and we trust, that it will be, "Impossible." In order to justify this statement we shall proceed to specify our objections to the scheme, trusting that, by so doing, some service may be rendered to a cause in which so many are now deeply interested, and which is undoubtedly of the highest importance to the community on account of the inestimable advantages to be derived from the teaching of the elements of experimental science, and especially of chemistry, in schools in a logical and systematic manner.

The issue of two companion volumes has many advantages: indeed we believe that in the future it will be thought essential to separate the instructions to a student stating what is to be done from any description or discussion of observations or inferences to be deduced from results, in order, as far as possible, to induce the habit of observing and of reasoning from observation; in no other way probably is it possible to force the student to become an independent observer and thinker, and to prevent the teaching of science from degenerating into mere cram, as is too frequently the case in schools. It appears to us, however, that in the earlier part of the "Practical Chemistry" Messrs. Muir and Carnegie do not sufficiently bear in mind their own intention, and that much of the matter would find a more fitting place in the companion volume.

In the "Practical Chemistry," we learn from the preface, "the aim has been to arrange a progressive course in which, as the experiments become more difficult, the reasoning becomes more close and accurate." But surely, in a scientific work, the reasoning should throughout be "close and accurate:" authors who make such a statement almost invite suspicion, and it is to be feared that in this case such suspicion is unfortunately not entirely unwarranted; the reasoning is indeed but rarely close, and not infrequently conspicuously absent. As a typical case, and as an illustration of the manner in which the experiments are usually set forth, Experiment 1, Chapter VI., p. 22, may be quoted:—

"Place a small piece of sodium in a little cage of wire-gauze attached to a glass rod. Fill a large test-tube with water and invert it in a small basin of water; hold the tube with one hand, and with the other bring the wire cage containing the sodium under the water, so that the gas, which at once begins to bubble through the water, passes into the tube and collects there. When the tube is full of gas, cover the mouth with the thumb, invert the tube, and bring a lighted taper to the mouth; the gas takes fire, and burns with a pale, almost non-luminous flame—the gas is hydrogen. Evaporate the water in the basin to dryness; the white solid which remains is a compound of sodium, hydrogen, and oxygen; it is called sodium hydroxide, or caustic soda. (The composition of this compound cannot be proved at present.) By the interaction of sodium and water, hydrogen and a compound of sodium with hydrogen and oxygen have been formed. Sodium is an element: *if this is taken as proved*, it follows that the hydrogen evolved as gas in the foregoing experiment, and also the hydrogen and oxygen which combined with the sodium, must have formed part of the water at the beginning of the experiment. (*Here we assume* that the material of the vessel was not chemically changed during the process.) Water therefore is a compound of hydrogen and oxygen."

What can be the educational value of an experiment thus described and discussed? That water *therefore* is a compound of hydrogen and oxygen only follows when a variety of assumptions are made. The tendency of such teaching is entirely in the wrong direction: the habit of *assuming* that such and such is the case is one which it is all-important to counteract by experimental teaching, and practical chemistry will never be of value as a rigid mental discipline unless the student be led from the beginning to demand and obtain proof of each successive link in a chain of arguments.

Again, the directions for Experiment 3, Chapter II., p. 7, are to heat copper in dried air, and to weigh the tube containing it before and after heating; the weight is found to increase, whence it follows that the metal has combined

with some other kind of matter, the most likely source of which is the air. We then read:—

"We must now *make two assumptions* which *can be, and have been, proved* by accurate experiments. We shall *assume* (1) that the air is a mixture of at least two gases called oxygen and nitrogen; (2) that water is a compound of two gases, hydrogen and oxygen. If then hydrogen is brought into contact with a heated solid substance and water is produced, it follows that oxygen must have been taken away from the heated solid by the hydrogen."

The student is therefore directed to heat the copper oxide previously obtained in a current of hydrogen, and finally to weigh the tube. The weight is the same as at the beginning of the series of experiments.

"You have therefore proved, *on the basis of certain assumptions*, that when copper is heated in air it combines with oxygen in the air to produce a new kind of matter called copper oxide; and that the weight of the copper oxide thus produced is greater than that of the copper from which it has been produced. *By experiments too difficult to be performed at present it can be proved* that the difference between these weights is the weight of the oxygen which has combined with the copper."

The effect of such teaching must be that the mind of a student with inborn intelligence, instead of having logic infused into it, will have become filled with profound contempt of chemical experiments; it is impossible that it should lead to the acquisition of precision of thought or judgment. In a properly chosen series of experiments everything should be proved; no assumption should be necessary.

"The arrangement of the course and the selection of the experiments are the outcome of the experience gained in teaching chemistry for many years" (preface). Having in mind the manifestos issued at various times by one of the authors, we naturally are led by this paragraph to expect an entirely original treatment of the subject. But, alas! we fear we may safely say that "what is true is not new, and what is new is not true"! Thus, in Chapter IV., which bears the imposing heading, "Conservation of Mass of Matter," we no longer meet with the classical candle experiment, and we confess that we little regret its banishment; but what have we in its place? An experiment in which zinc is dissolved in diluted sulphuric acid, the hydrogen being retained in a tube; and a second, in which marble is dissolved in acid, the carbon dioxide being prevented from escaping by potash solution. We venture to think that neither experiment is calculated to impress the beginner, and that the only proper demonstration in this case is by some form of combustion experiment in which there is an apparent destruction of matter; but we hold that it is far better simply to lead the student to observe that in every case of apparent disappearance a new form or forms of matter are produced, and to postpone any attempt to teach the law of the "conservation of matter" until a time when the results of the gigantic labours of men like Stas can be appreciated. Again, is a *blue crystalline solid* obtained (Experiment 3, Chapter III.), on dissolving copper in sulphuric acid and evaporating the liquid nearly, but not quite, to dryness—we presume in a water-bath, as directions have previously been given (p. 3) *always* to use a water-bath, unless otherwise directed. In Experiment 8, Chapter V., the student is directed to electrolyze water containing a little sulphuric acid, and the accompanying cut represents a basin in which tubes are inserted over electrodes connected with *two* bunsen cells; in the figure the bunsens are 7/16 of an inch in diameter, the basin is 1 inch across at the base, and the liquid column 3/16 of an inch deep. Assuming the bunsens used to be 4 inches in diameter, the basin would be 7 inches across at the base, and the liquid $1\frac{5}{16}$ inches deep; there would consequently be a fairly respectable quantity of water to electrolyze. Yet, at p. 7 of the "Elementary Chemistry" we read: "If the process is continued, the water will at last entirely disappear, and in place of it we shall have two colourless gases. This result of "experience gained in teaching chemistry for many years" is indeed remarkable; the store of energy in two bunsen cells is truly marvellous, and we had not previously realized how great is the capacity of tubes such as are figured. At p. 3 the direction is given to add sodium to water in a basin, and, when the sodium is all gone, to place the basin on a *water-bath* and evaporate until the water is wholly removed. A white hard lustreless solid called caustic soda is said to be obtained. Here, again, the authors' experience is probably extraordinary. We are also under the impression that the student would be disappointed with the result of the experiment figured on p. 30 of the "Elementary Chemistry."

Next, as to the arrangement of the course. What strikes us most, and what we are least prepared to excuse, in the "Practical Chemistry," is the entire absence of anything approaching to a *systematic* arrangement. Part I. consists of 102 pages, and the chapters bear the following headings: I. Chemical and physical change; II. Elements and not-elements; III. Not-elements divided into mixtures and compounds; IV. Conservation of mass of matter; V. Methods of bringing about chemical changes; VI. Chemical properties of water; VII. Classification of oxides; VIII. Acids and salts; IX. Classification of salts; X. Alkalis, and alkaline hydroxides; XI. Reactions between acids and salts; XII.–XV. Classification of elements; XVI. Conditions which modify chemical change; XVII. Oxidations and reductions; XVIII. Strong and weak acids. In Part II. (78 pages) the chapters are headed: I. Laws of chemical combination; II. Equivalent and combining weights; III. Molecular and atomic weights; IV. Dissociation; V. Reacting weights of compounds determined by chemical methods; VI. Chemical change; VII. Chemical classification. At the outset the authors are strictly conservative, and in the most orthodox manner possible in the first three chapters instruct the student to dabble with a variety of substances never heard of for the most part in ordinary life, and to this we most strenuously object. We are convinced that the only way of beginning to teach chemistry, if the object be to cultivate the faculties of experimenting, observing and reasoning, is to deal with familiar objects and phenomena; and that at the very outset, after as far as possible determining the properties of familiar objects by means of ordinary appliances, we ought to set our students to analyze. We hold that air and the phenomena of combustion should be first studied: the composition of air should be determined, and oxygen should be *discovered* by the student. This we

believe to be both historically and scientifically the correct method. The composition of water should next be qualitatively ascertained. It is a *sine quâ non* that the experiments made with the object of solving such problems be throughout logically interrelated; each experiment should be suggested by the experiment or experiments previously made, and should be made with the object either of verifying or extending the information previously gained. When a student is told to perform experiments selected by the teacher for no apparent reason and merely with the object of demonstrating some particular point, their value as a logical exercise is practically *nil*. In solving such problems as the composition of air and water, &c., the student insensibly realizes the distinctions which are to be drawn between mixtures, compounds and elements, and soon learns to appreciate the characteristic difference between chemical and so-called physical change; but we hold it to be a positive advantage not to insist too strongly on the presumed difference now that it is becoming probable that many phenomena hitherto regarded as physical essentially depend on a change in molecular composition.

These remarks apply also to Chapter IV., already referred to, and to Chapter V.; in this latter, the slain of previous chapters are rekilled. Chapter VI. is headed "Chemical Properties of Water." Experiment 1 was quoted above and appears to be intended to serve as proof of the composition of water. Experiments 2–7 have nothing whatever to do with water, but relate to the preparation and properties of hydrogen and oxygen. Experiment 8 involves the examination of the residues from the preparation of hydrogen and oxygen. Then follows the oracular sentence: "Water is a compound of hydrogen and oxygen; let us examine a few of its properties." Experiment 9 therefore directs the student to add powdered copper sulphate crystals, potassium nitrate and tartar emetic to separate portions of water, and to take note that water acts on these as a solvent, inasmuch as their composition is not changed by it. Experiment 10 consists in adding anhydrous copper sulphate, and also solid sulphur trioxide to water; in both cases, it is found that the water not only dissolves but acts upon the substances. Here the chapter ends: we question whether the most conscientious performance of the experiments will lead the student to acquire any clear conception of the "chemical properties of water."

Thus far we have confined our remarks to the opening chapters, it being our opinion that these are all-important in a work which purports to teach the elements of chemistry. But there is much in the arrangement of the remainder of the book to which we venture altogether to take exception. Thus a fatal error of judgment has led the authors to postpone the experimental discussion of the laws of chemical combination and of equivalent and combining weights, as well as of molecular and atomic weights, to Part II., placing in advance of these all-important subjects a variety of matters—among others a discussion of the properties of the various elements classified in groups in accordance with the periodic law—which cannot properly be considered without a fairly complete knowledge of the laws of chemical combination. It is obvious that the authors to some extent recognize their mistake, as the order is different in the *companion* volume, the laws of chemical combination, and symbols and formulæ being discussed in Chapters V. and VI.

The "Elementary Chemistry" contains a third part dealing with subjects which are only touched on in the companion volume; this part is to be used in conjunction with portions of the "Principles of Chemistry," by one of the authors. Chapter I. of this part should have been included in Part I.; the remaining chapters ought never to have been introduced into an "Elementary Chemistry," and are obviously only included because of the senior author's well-known tendency to worship physical constants. Thus Chapter II. is headed Dissociation, and directions are given for the performance of Lemoine's experiments on the dissociation of hydrogen iodide, and of Horstmann's on ammonium carbamate: the authors evidently to some extent foresee the probable result of making such experiments, as, in summing up those on hydrogen iodide, they say: "The results of your experiments *ought* to show" that such and such is the case. How often would they? Chapter III. bears the title, "Relative Affinities of Acids," and in it experiments are described illustrating Thomsen's and Ostwald's methods; the same subject is briefly referred to in Chapter XVIII., Part I. The main objection to this chapter is that students of elementary chemistry are incapable of performing such experiments with sufficient accuracy. Moreover, it cannot yet be admitted that the conception introduced by Thomsen is warranted: until the part which the water plays is determined, neither Thomsen's nor Ostwald's results can be accepted as furnishing estimates of the relative affinities of acids for a given base. A similar remark applies to Menschutkin's etherification experiments, the repetition of which is directed in Chapter IV.: the complete interpretation of these is yet to be given.

Nothing is farther from our intention than the desire to disparage the study of so-called physical properties—on the contrary, we hold it to be of primary importance that a *proportionate* amount of attention should be devoted by students of chemistry to the physical side of their science; but let them learn before all things to regard the phenomena from the true chemist's point of view. Chemistry is to a large extent an art: a large number of relationships and peculiarities which are obvious to the skilled chemist will probably always elude mathematical treatment; it appears, indeed, to be as impossible to give formal expression to them by means of physical constants as it would be to define the work of a great painter after spectroscopic analysis in terms of wave-lengths. Especially have we felt this to be the case on reading through Ostwald's invaluable work: it has frequently struck us that he has perhaps unduly forgotten his art as chemist in the exercise of his great technical skill in determining and setting forth physical constants, the result being a picture which fails to satisfy. But it is not to be denied that chemists as a class have not yet acquired that belief in the power of physicists to help them forward which, with or without reason, is demanded of them; and this is not difficult to understand. The establishment of the doctrine of structure—the great achievement of modern chemistry—is the outcome solely of chemists' labours; in this particular case, the study of physical properties has served to confirm the conclusions of chemists, but there is nothing to

show that it could ever have led to them. And all recent attempts to directly apply the results of physical determinations have proved most unfortunately barren of results: a striking example of this is afforded by the complete failure which appears to have attended Thomsen's attempt to deal with the vast mass of thermal data accumulated by his unwearied study of carbon compounds. Chemists have not as yet received much assistance from physicists: the determination of physical constants has served to give precision to chemical statements, but little else; and it is not probable that it will ever be otherwise. In fact, the attitude of the two classes of observers towards natural objects is different, and appears to be somewhat as follows. The physicists are much like a party engaged in the investigation of a strange nation: they walk through the streets of its towns and most carefully observe how the houses are externally constructed and arranged, and study the traffic in the streets, but they do not enter the houses or take note of the mental peculiarities of the people. The chemists, however, enter the houses: they observe their internal structure, they determine the influence of this internal structure on the character and occupations of the inhabitants, of whose mental peculiarities they also endeavour to gain clear conceptions. Those chemists who are satisfied to merely cross the thresholds without continuing their studies and researches, and who therefore have much to learn before they can appreciate the labours of their more active and curious brethren, have no right to take upon themselves the functions of law-givers.

Lastly, a few words regarding the illustrations. It will no doubt be said that these are only diagrammatic; that students are to perform the experiments themselves and therefore will become acquainted with the actual apparatus. But even diagrams should be drawn to scale: Figs. 37, 38, and 43, are illustrations which show how frequently this is not the case: if such very wide-mouthed flasks were always used as are pictured in most of the diagrams a small fortune would be expended in corks. An elementary work should be properly illustrated by drawings which fairly represent the actual apparatus, as such a book will necessarily fall into the hands of those who have no knowledge of apparatus, and therefore need guidance.

From our remarks it will be gathered that we entirely disapprove of the "Practical Chemistry" as a book for beginners: we do not recommend it even to more advanced students. Teachers will no doubt be able to cull a few useful hints from it, although there is a striking absence of originality or novelty in all practical details.

We have little to say of the "Elementary Chemistry." It is an infinitely better book than the companion volume, and a fairly advanced student will find in it much information of interest and value not to be met with in any other current work of the kind. But it is not an elementary chemistry in any proper sense of the term, and, as in the companion volume, the attempt is made to crowd far too much matter into the space at disposal.

In expressing our opinion thus plainly, we have been guided by the desire to do something to stem the ever-flowing tide of so-called elementary text-books of chemistry; these are mainly the outcome of the existence in this country of a vast amount of pseudo-chemistry, and of little true chemistry, and the very existence of such books is doing an infinity of mischief in helping to perpetuate the evil. We believe that it would be of great advantage to chemical science to form an Association to prevent the further publication of elementary works other than such as had been carefully revised and approved of by a Publication Committee of the Association. The harm done by unsystematic and illogical teaching, and by vague experimenting, can never be repaired, and it is incumbent on an author to ponder the meaning and effect of every word, line, and sentence of an elementary text-book.

The authors of the "Elementary Chemistry" say that the book does not profess to be a descriptive catalogue of chemical facts regarding the properties of the individual elements and compounds. But until a satisfactory practical elementary chemistry shall have been written, it is far better that students should gain simply an exact knowledge of chemical facts, and that in their practical work they should be guided by books which we all acknowledge to be sound, though we may think that they are far too restricted in range. Let each school purchase as many copies as possible of a grand old standard work such as Miller's large "Inorganic Chemistry," full of honest common-sense and all but free from fads, and let this serve as the book of reference. A fair understanding of the broad principles which underlie the science may be gained from books such as Cooke's "New Chemistry," and Wurtz's "Atomic Theory," both master-works in their way.

H. E. A.

CHINESE CIVILIZATION.

China: its Social, Political, and Religious Life. From the French of G. Eug. Sîmon. (London: Sampson Low and Co., 1887.)

THE reader who takes up this volume, expecting to find it an ordinary popular sketch of Chinese life and manners, similar to dozens of others which have gone by and dozens which are doubtless yet to come, will be totally mistaken. For in place of a colourless account of China—if any account of that wonderful country with its marvellous civilization could be written wholly devoid of colour,—and a jejune outline of the peculiarities of the Chinese, the reader will find here one of the most closely reasoned, original, and powerful defences of the Chinese social and political system that have ever been published in Europe. Writers of eminence, indeed, there have been who have selected some special peculiarity of Chinese religion, society, or politics, and have held it up to the West as worthy of imitation, and as a mark of profound wisdom; but M. Sîmon defends Chinese polity and civilization all along the line. He lived in China as a French official in the critical years succeeding the war of 1861-62; he travelled widely, and he observed keenly. This volume was not written in the first flush of pleasure and surprise at the strange and wonderful things he saw about him; he returned home, and has had ample time to correct first impressions, to review conclusions formed on the spot by the light of subsequent experience and knowledge, and years afterwards he is able to tell to the West that, as of old, the wise men still come from the East, and that the highest product of the human mind is to be found in the civilization of China. The most civilized

State is that "in which on a given area the largest possible number of human beings are able to procure and distribute most equally amongst themselves the most well-being, liberty, justice, and security." Measured by this standard, China is pronounced to be the most highly civilized country in the world, and the Chinese have this peculiarity—that, while modern nations are only the collateral successors of those of antiquity, China is the direct heir of the generations which created it. "Its history shows the phenomena of heredity in regular succession, neither modified nor obstructed by change of medium, with the evolution of events and ideas —an evolution as regular as that of living beings, freely proceeding unshaken and untroubled by any exterior influence, by which its direction might have been altered or its development retarded; and it is here, I repeat, that we find the deep and original interest of China, and perhaps also the secret of her extraordinary longevity." The book is a study of the progress and organization, in short of the civilization, attained by humanity under such conditions of liberty and development. The student in this case is full of love of his subject, and this no doubt is a great advantage, although it has its disadvantages also. M. Sîmon tells us of a land flowing with milk and honey, moral as well as material. Nothing that he has seen is inharmonious or out of place; everything is for the best, and has had the best effects. Chinese civilization is not a dead, rotten branch, as it is usually represented to be, but a living active power for good; in fact, "nowhere in the world is there such proof of force and vitality" as in the Chinese character and in Chinese civilization.
